Cross-correlograms frequently show a narrow peak on a broader pedestal (e.g., Fig. 2a) especially when units are recorded on the same electrode (Eggermont 1992; Nowak et al. 1995). The broader pedestal is typically the result of covariance in firing rate between the two spike trains, e.g., caused by the stimulus, whereas the sharp peak indicates event synchrony, i.e., firing coincidences (Neven and Aertsen 1992). The rate covariance under spontaneous conditions can easily be estimated by calculating a cross-correlogram for 50 ms bins that slide in 10 ms steps (Eggermont and Smith 1995). Subtracting the rate covariance from the overall correlogram will result in the event correlation.

This generally assumed model, even if correct, may still result in an inaccurate estimation of the true event correlation. Staude et al. (2008) decomposed the raw cross-correlation as the sum of the modulation rate covariance and spike coordination based on the mean conditional covariance of the processes given the rates. Both, rate covariation and spike coordination alike, contribute to the raw correlation function by triangular peaks. This separation does not always have to result in a broad triangular peak for rate correlation and a narrow one for spike correlation; at least in their procedure, the reverse can be possible as well. Staude et al. (2008) stated “without prior knowledge of the underlying model class, rate estimation will most likely be suboptimal. The resulting predictor leaves a residual central peak in the corrected correlation function, which is likely to be wrongly interpreted as spike coordination.”

Stimulus-Dependent Neural Correlation

An example, exhibiting stimulus-dependent correlation, is provided in Fig. 3. As discussed above,

Correlation Analysis of Parallel Spike Trains, Fig. 3 Unit pair with stimulus-dependent neural correlation. (a) and (b) dot displays of single-unit activity to tone pips with carrier frequencies in the range 100–3200 Hz. The stimulus inhibits the unit shown in (a), whereas it activates the unit shown in (a). (c–f) simultaneous and nonsimultaneous (shift predictor; shaded) cross-correlation histograms for a variety of stimuli. Bin width is 4 ms. (From Epping and Eggermont 1987)

this may potentially result from using the invalid assumption of “neural synchrony equals the sum of stimulus correlation and neural correlation.” The two spontaneously active units shown were recorded in the auditory midbrain of the grass frog on electrodes with an estimated tip separation of 130 μm . The spontaneous rates were 0.34 (A) and 2.5 (B) spikes/s, respectively. Their spectro-temporal sensitivities, represented as dot displays of neural activity, as determined with tone pips presented once per second, are shown in Fig. 3a, b. The spontaneous activity of unit a was suppressed by frequencies below 1000 Hz (Fig. 3a), and the very low spontaneous activity did not result in many spikes in the 256 ms time window, whereas unit b was activated in this frequency range with a latency of 67 ms (Fig. 3b). Neural synchrony histograms and shift predictors (shaded) of spontaneous and stimulus-evoked activity are shown in Fig. 3c–f. For spontaneous firing, the neural synchrony and shift predictor are flat and hardly different (Fig. 3c). For tone-pip stimulation, the shift predictor (Fig. 3d) shows a decrement due to the antagonistic (suppression vs. activation) stimulus influence on the two units. Just visible on top of the shift predictor is a small, rather symmetric peak around the origin, likely indicating shared neural input. The shift predictor to sinusoidally amplitude-modulated (AM) 200 ms tone bursts is broad (Fig. 3e) with a sharp ($W = 6$ ms) peak of the neural synchrony visible on top. Figure 3f shows results for a low-pass noise-modulated tone. One observes an asymmetrical peak with flanking valleys due to the autocorrelation structure of the individual spike trains. The two units responded antagonistically to the tone-pip stimulus, but more alike to the other stimulus ensembles; e.g., when stimulated with sinusoidally AM tone bursts (Fig. 3e) with a carrier frequency of 500 Hz, the units both were excited by a band-limited range of AM rates around 100 Hz. This suggests that the unit pair exhibits stimulus dependencies of both stimulus-induced cross-correlations as revealed by the shift predictor as well as neurally mediated cross-correlations because of changes in form and width of peaks in the neural synchrony as compared with the shift predictor.

Correcting for Common Input Firing Periodicities and Firing Rates

According to de la Rocha et al. (2007), the stimulus-corrected cross-correlation coefficient for common input still depends on the geometric mean of the firing rates of the two neurons, both in cortical slice recordings and in their simulated data. This effect was also visible for *in vivo* recordings from visual cortex (Krüger 1991), and it was used to argue that nearly all of the cortical cell correlations resulted from common retinal input. This suggests that additivity-corrected procedures are inadequate and that multiplicative interactions of stimulus and spontaneous firing activity occur. This can be corrected for by a deconvolution procedure as described below.

The example shown (Fig. 4) was based on spontaneous multielectrode recordings from primary auditory cortex in an anesthetized cat where the EEG showed spindle waves in the frequency range of 8–10 Hz. In anesthetized animals (sleep), spindle oscillations are frequently observed. The oscillations likely reflect common input as the correlograms typically appear symmetric around zero lag, so their effect should disappear in the corrected correlogram using a deconvolution procedure. These periodic oscillations are reflected in the firing times of the spike trains and in the oscillatory character of the cross-correlogram (red curves). This effect was corrected by deconvolving the cross-correlation function by the geometric mean of the autocorrelation functions of the two spike trains (Eggermont and Smith 1996). The corrected result is shown as the blue curves. One notices also the strong contribution (>50%) of these spindle-related correlations on the peak value of the cross-correlogram.

The deconvolution procedure is carried out in the frequency domain by taking the Fourier transform of $C_{xy}(\tau)$, resulting in the cross spectrum $S_{xy}(f)$ and dividing by the square root of the product of the two Fourier-transformed autocorrelation functions, i.e., the power spectra. This gives the complex coherence:

Correlation Analysis of Parallel Spike Trains, Fig. 4 The deconvolution-based correction procedure eliminates the oscillatory aspects resulting from anesthesia-induced spindle oscillations in auditory cortex. Here we show all pair correlations between the spike activity between two eight-electrode arrays; one array with electrodes numbered 1–8 and the other with electrodes numbered 9–16. The red curves show the raw

cross-correlograms for spontaneous activity in cat primary auditory cortex. The blue curves represent the corrected cross-correlograms. All units showed an oscillatory auto-correlation at the same (spindle) frequency, and the effect thereof is eliminated using the deconvolution procedure. All correlograms are scaled to the peak of the raw cross-correlation coefficient value (the red curve), which is shown in each panel. (From Eggermont (unpublished))

$$\gamma_{xy}(f) = \frac{S_{xy}(f)}{\sqrt{S_{xx}(f)S_{yy}(f)}} \tag{15}$$

An inverse Fourier transform results in the corrected “correlation coefficient” (Eggermont 2006).

Correlation and Connectivity

In general there is no unique relationship between known connectivity and observed cross-correlation (Meyer and van Vreeswijk 2002). Correlations are in principle determined uniquely by connectivity, including the strengths and delay

dependence of the connections. From the neural correlation one can, under certain assumptions about the integration of neural input and the shape on the neuron’s response curve, estimate the strength of the neural interaction. Because the estimate of the peak neural correlation is very sensitive about the shape of and working point on the neuron’s response curve (Melsen and Epping 1987), it is generally not permitted to equate the strength of the neural correlation estimated from extracellular recordings with the strength of the neural interaction. When an actual stimulus is applied, one of its effects, especially for cortical neurons, will be to shift the neuron’s working point, and apparent changes in neural

correlation may be found without a concomitant change in the strength of the neural interaction (Aertsen and Gerstein 1985; Melssen and Epping 1987).

The simplest interactions shown by a pair of neurons are that one neuron makes a direct excitatory or inhibitory connection with the other or that both neurons share a common excitatory or inhibitory input. It has been shown in simulation studies that common excitatory input and common inhibitory input result in a peak in the cross-correlogram around zero-lag time. Reciprocal excitatory and inhibitory input to the neurons provided by the same source result in a central dip in the cross-correlogram (Moore et al. 1970). Unilateral excitation shows a peak shifted to positive lag times, and unilateral inhibition shows a dip at positive lag times.

In auditory cortex evidence for direct excitation or inhibition has been scant, unless the neuron pairs were recorded on the same electrode, and nearly all correlograms are of the common input

type (Eggermont 1992, 2000). In visual cortex several interaction types have been shown for recordings with dual electrodes from cells at different depth in the same cortical column (Toyama et al. 1981). However, more variety in correlogram shapes was found in the auditory midbrain (Epping and Eggermont 1987). In the examples shown in Fig. 5, we show (A) stimulus-induced common excitatory effects without neural correlation for two units recorded on the same electrode and (B) stimulus-induced common suppressive effects for a pair recorded on electrodes separated by 130 μm . In both cases the shift predictor is equal to the neural synchrony. Weak stimulus-induced activation combined with a direct excitatory effect from one neuron upon the other recorded on the same electrode (C) is inferred because the shift predictor is hardly visible and the peak of the correlogram is displaced by 6 ms from the origin and highly asymmetrical. This is interpreted as a unidirectional excitatory influence of unit 1 on unit 2. In these three

Correlation Analysis of Parallel Spike Trains, Fig. 5 Potential functional connectivity underlying cross-correlation functions. Simultaneous and non-simultaneous (shift predictor; shaded) cross-correlation histograms are superimposed. (a) Neural synchrony, incremental correlogram. (b) Neural synchrony, decremental correlogram. (c) Unidirectional excitatory input. (d) Neural shared input. (e) Unidirectional excitatory input.

(f) Neural shared input. Stimulus-driven activity in (a–d); spontaneous activity in (e) and (f). Note different time scales. Simple connectivity schemes that can account for the observed phenomena are shown as insets. S, stimulus; 1, neuron 1; 2, neuron 2; u, unobserved neuron. Open and closed triangles indicate excitatory and inhibitory connections, respectively. (From Epping and Eggermont 1987)

examples, the stimulus consisted of random frequency tone pips presented once per second. Part D shows stimulus-induced (Poisson-distributed clicks) common input for a pair recorded with electrodes separated by 290 μm putatively via an unobserved neuron (D), because it has a pronounced shift predictor. For two spontaneous recordings (E, F), reason for the flat shift predictors, unidirectional excitatory input was observed for a single-electrode pair (E) and common input for a dual-electrode pair (separation 160 μm ; F). The highly asymmetrical peak of the neural synchrony displaced from the origin in part E indicates that unit 1 exerts a unidirectional excitatory influence on unit 2. However, there may be a complication due to the dead time of the spike-sorting procedure, and it may well be a common input neural correlation as well. This is a known drawback of using sorted units recorded on the same electrode.

Effects of Spike Sorting on Pair Correlations

Multiunit (MU) recording is common in structures with high cell densities and especially using multielectrode arrays. Spike sorting can result in well-sorted units, but by no means can one be sure that one is dealing with single units (SU), that is, only the case when doing intracellular or patch-clamp recordings. Evidence from neural modeling suggests that interpretation of neural correlations from multiunit recordings may be ambiguous as it is not a linear combination of correlations for the various single-unit pairs (Bedenbauch and Gerstein 1997; Gerstein 2000). However, changes in single-unit correlation strengths will be accompanied by comparable changes in the correlation between multiunit activities as shown in Eggermont (2000). Thus, if a number of single units contribute to each multiple single-unit recording, the changes in the MU values will be positively, but nonlinearly, related to those for the corresponding SU ones. So if SU correlations go up, so will the MU correlation. The only difference is that the R-values are larger for

MU than for the corresponding SU ones but smaller than the sum of all the relevant SU pair R-values. Trying to estimate functional connectivity from sorted multiunit activity is not encouraged.

Correlations and the Brain

Calculating a shift predictor or any other type of stimulus predictor is a way to extract the effects of stimulation on the effective neural connectivity despite the drawbacks that we discussed. However, as we have previously argued (Tomita and Eggermont 2005), it is unlikely that the nervous system performs a correction for stimulus-induced correlation as estimated by the various predictors. It is the actual spike coincidences, i.e., the neural synchrony, that are affecting the potential for firing in a target neuron and not the stimulus-corrected ones. Thus, raw correlations may effectively estimate those coincident firings between neurons that could play a role in neural population coding of sound. The effect of removing common periodicities in spike firing and common bursting activity from the cross-correlation can be justified because these contributions typically do not occur, or occur much less, in awake animals and are often the result of using anesthesia. Nevertheless, in our data for 15-min steady-state stimuli, the effects of a stimulus correction based on the shift predictor are minimal (Fig. 6), so using the stimulus-correction procedure has minimal effect on the interpretation of the data. However, for transient and optimal stimuli, the stimulus correction can be extensive and even remove all correlation (Eggermont 1994), so in this case one has to consider what the correlation estimate needs to support. If one is concerned with estimating connectivity or deciding which wiring scheme is most likely, then both stimulus corrections and corrections for common, network-induced, activity need to be performed. If one is concerned with how the brain performs its task in vivo, then these corrections may obscure the very aspects one wants to understand.

Correlation Analysis of Parallel Spike Trains, Fig. 6 This set of three cross-correlograms illustrates the stimulus-correction procedure applied to spike trains recorded from primary auditory cortex in the cat during a 900 s long random frequency stimulus where the second half was equal to the first. Stimuli were tone pips presented randomly in frequency and time with an overall rate of 28/s across 7 octaves (112 frequencies, so an average rate of 0.25 frequencies/s). The recording comprised 2 arrays of 16 electrodes each. Here we show the pair correlation between two neighboring electrodes separated by

0.5 mm. The uncorrected cross-correlation coefficient function is shown in solid line; the peak cross-correlation is approximately 0.082. The frequency tuning of the two recording sites was nearly identical, yet the stimulus correlation obtained as a shift predictor (dashed line) shows only modest stimulus locking. The stimulus-corrected cross-correlation coefficient function is shown in a connected dot line. Cortical Columns and Neural Population Models

► Mesoscopic Anatomy and Neural Population Models

Cortical Columns, Models of

Sean Hill

Brain Mind Institute, Lausanne, Switzerland

Definition

A cortical column is a module in the neocortex, approximately 300–600 μm in diameter, composed of many minicolumns coupled by short-range horizontal connections. Neurons within a column often share dynamic response properties. In general, a column is part of a continuous sheet of neocortex, where the boundaries of individual columns cannot be determined by anatomy alone, although there are exceptions such as the barrel field columns in rodent neocortex. Columns with similar response properties are often connected by long-range horizontal connections. Numerous efforts have been undertaken to develop computational models of the cortical column, which is often equated with the quest to identify the fundamental computational unit of the mammalian brain. These efforts span from highly simplified “mean-field” models that model interactions between homogeneous cell populations to detailed biophysical models with heterogeneous neuron morphologies and diverse electrophysiological behavior. Orientation selectivity in the

primary visual cortex is an example of a computation performed by a cortical column, which has been observed experimentally and modeled computationally. However, a common goal of modeling the cortical column is to identify a more general putative canonical computation occurring throughout the neocortex.

Detailed Description

Background

The neocortex originated in a mammalian ancestor approximately 250 million years ago and its evolution has been critical for the emergence of human cognition and behavior. The types of neurons and their local synaptic connectivity in different parts of the neocortex appear to be variations on a basic stereotypical circuit design. Lorente de Nó (1938) was the first to suggest that “vertical chains” of neurons traversing the six layers of the neocortex formed elementary functional units: “all the elements of the cortex are represented in it, and therefore it may be called an elementary unit, in which theoretically, the whole process of the transmission of impulses from the afferent fibre to the efferent axon may be accomplished.” Vernon Mountcastle and colleagues subsequently showed that neurons separated by a horizontal distance of less than a millimeter share similar response properties (Mountcastle 1957; Mountcastle et al. 1957; Powell and Mountcastle 1959). The term “column” was proposed by Mountcastle who suggested “there is an elementary unit of organization in the somatic cortex made up of a vertical group of cells extending through all the cellular layers” (Mountcastle 1957). The hypothesis is that the column is a functional cortical module, composed of minicolumns, and approximately 300–600 μm in diameter, which is replicated throughout the neocortex as the primary computational unit. The evolutionary expansion of the neocortex is thought to have occurred as a result adding additional cortical columns rather than increasing the size of the cortical column (Rakic 1995). Working in cat visual cortex, Hubel and Wiesel demonstrated functional cortical columns with a

diameter of around 0.5 mm (Hubel and Wiesel 1977). Later studies showed that different patterns of stimuli produced different functional architectures with different spatial fidelity (Mountcastle 1998). In Neuroscience, there has been difficulty adhering to a single definition of a cortical column leading to debate and confusion about both its existence and function (Horton and Adams 2005). However, a common goal of modeling the cortical column is to identify a putative but general canonical computation and the specific neuronal mechanisms that underlie the emergence of diverse functional architectures throughout the neocortex.

Modeling Approaches

An early qualitative model of cortical circuitry was proposed by Hubel and Wiesel (1962) to describe the mechanisms underlying simple and complex cell responses in nonhuman primate cortex based on strongly tuned convergent thalamocortical input.

Douglas and Martin (1991) provided the first canonical microcircuit model from their studies on visual cortex in the cat. This model was based on microanatomical studies and in vivo intracellular recordings. It provided an account of the intracellular responses to pulsed stimulations in terms of an inseparable combination of excitatory and inhibitory responses of three basic populations of neurons. Their model proposed that thalamic input is not the major source of excitatory input to cortical neurons, and instead intracortical input was the dominant source of excitation.

Somers et al. (1995) implemented a large-scale computational model of orientation selectivity in cortical simple cells that demonstrated that sharp orientation tuning could emerge from local recurrent intracortical excitation at the columnar level and be balanced by nonspecific inhibition with only weakly tuned thalamocortical excitation.

Much work has been focused on explaining the function of the cortical column during wakefulness. Hill and Tononi (2005) focused on the observation that the cortical column is multifunctional and can exhibit strikingly different functions in

wakefulness and sleep. Their large-scale model of thalamocortical visual circuitry was based on point neurons organized in repeating columnar structures with patchy long-range connectivity and illustrated how columns transition between spontaneous activity and orientation-selective responses during wakefulness and slow oscillations during sleep.

Traub et al. (2005) has developed a model of a single thalamocortical column (in this case a cortical minicolumn coupled with thalamic and reticular thalamic neurons) based on biophysical models of neurons with schematic morphologies employed to more accurately capture the positioning of synapses on different compartments of neurons. This model exhibited a broad range of oscillatory, epileptic, and sleeplike phenomena.

Launched in 2005, the Blue Brain Project (bluebrain.epfl.ch) proposed a data-driven process to construct highly detailed biophysical models of the cortical microcircuitry that underlies a column (Markram 2006) using extensive measurements of the young rat (P14) somatosensory cortex, including single-cell gene expression, whole-cell patch clamp electrophysiology, morphological reconstructions, synaptic connectivity and plasticity, and more. The models capture the experimentally observed diversity and composition of 55 morphological and 12 electrophysiological classes. The group has since shown that the resulting models can be used to predict synaptic connectivity patterns (Hill et al. 2012) and cellular contributions to the local field potential (Reimann et al. 2013).

A detailed anatomical model of an average barrel column within the somatosensory cortex of the rat has been proposed by Helmstaedter et al. (2007). The barrel cortex provides an example where both the anatomical and functional cortical column is well defined. Work from this group has led to detailed anatomical reconstructions that take into account the numbers and distribution of the somata, dendrites, and thalamocortical synapses of nine cortical cell types, soma location, dendritic morphology, synapse innervation, and predictions of synaptic connectivity for a thalamocortical circuit in the rat vibrissa cortex (Oberlaender et al. 2012).

Summary

A broad diversity of approaches has been taken to modeling the cortical column. In the end, they share a common goal of understanding whether or not there is a canonical computation performed by cortical microcircuitry and what are the mechanisms that govern and generate it.

Cortical Function, Normative Models of

Jochen Triesch
Frankfurt Institute for Advanced Studies,
Frankfurt am Main, Germany

Definition

Normative models of cortical function are a class of models that are related to or derived from a well-defined mathematical objective function. They allow to understand the brain's solution to a certain computational problem in relation to an optimal solution that maximizes the chosen objective function, if such a solution can be found.

Detailed Description

Normative models of cortical function are much like other computational models of the cortex.

They try to describe and explain experimental data and make predictions that can be used to falsify them (Dayan and Abbott 2001). But rather than directly asking how the brain solves a particular computational problem, one first asks what the *optimal solution* to this problem is. Then the actual solution embodied in the brain may be understood as a specific implementation of this optimal solution or a reasonable approximation to it. Thus, by using normative models, one approaches the question of how the brain works by first asking how the brain *ought to work*. The great strength of this approach is that it can lead to an understanding of brain function at a deeper level. Rather than only describing *how* something works in the brain, normative models reveal *why* the brain may be operating in this way. Normative modeling approaches are not restricted to *cortical* function, but may be used at essentially all levels of nervous system modeling and beyond.

There is a wide range of existing and conceivable normative models of cortical function due to the vast range of functions in which the cortex is involved. These include perception, cognition, memory, and motor control. In each of these areas, normative models can be used to try to better understand aspects of cortical function. While the cortex is clearly involved in all of the mentioned functions, it is worth noting, however, that all of these functions are also present in animal species without any cortex. In such species, similar computational functions may be implemented in a very different way. In much the same way as different computer algorithms or different implementations of the same algorithm can solve the same problem, different nervous system structures in different species might have evolved to solve the same problem in different ways.

A generic task for a perceptual system that may be implemented in sensory cortical areas is to represent the sensory signals in an efficient way. Sensory stimuli are typically represented by large populations of neurons in sensory cortical areas. Normative models of sensory coding ask how a population of neurons can encode a given class of sensory signals optimally. To this end, certain assumptions about noise in the sensory signals or the processing neurons or a limited energy

budget may be considered. Sparse coding models and predictive coding models are popular examples of normative models of sensory coding.

Another generic computational problem in which the cortex is involved is to make inferences from incomplete and noisy sensory inputs. Examples are recognizing the face of a friend in a poorly lit room or following a conversation in a noisy environment. A popular normative framework for describing how such inferences *ought to be* made is that of Bayesian inference. Correspondingly, much current research aims to understand learning and information processing in the cortex from the perspective of Bayesian inference and attempts to elucidate whether the cortex may implement a specific kind of Bayesian inference and learning algorithm or some approximation to it. Correspondingly, Bayesian inference is a major topic in contemporary computational neuroscience (Doya et al. 2007).

Another generic computational problem in which the cortex is also involved is to make decisions and control our actions. A popular normative framework for describing how decisions *ought to be* made in an optimal way and how an agent *ought to* select actions are those of decision theory and reinforcement learning. Consequently, much research tries to address how the cortex and other brain structures such as the basal ganglia may be implementing approximations to optimal decision making or specific reinforcement learning algorithms.

Overall, normative modeling approaches have already proved to be very fruitful in providing a deeper understanding of brain function in general and cortical function in particular. Beyond merely describing *how* the cortex operates, they reveal *why* this way of operation is appropriate or even optimal.

Definition

The term “cortical map” refers to the existence of a nonrandom relationship between the position of a neuron in the cerebral cortex and the value of some property that can be assigned to it on the basis of physiological or anatomical tests. Typically the property in question is a receptive field parameter of a sensory neuron, e.g., the position in space of the receptive field of a visual sensory neuron, or the color of a stimulus that activates it, but it might also be a projective field, e.g., the position in the body of a muscle or group of muscles activated by neurons in motor cortex, or, more speculatively, some aspect of knowledge or behavior coded for, or produced, by activity in single neurons or groups of neighboring neurons (perhaps as measured by fMRI experiments). A further qualification is that map properties often remain constant in value with depth in the cortex and vary only with lateral (equivalently tangential) position. This property, termed “columnar organization,” (Hubel and Wiesel 1977; Mountcastle 1998) means that the cortex

is normally treated as a two-dimensional array for modeling purposes. “Activity-dependent development” in the context of “cortical maps” refers to a class of computational neuroscience model that seeks to explain the development of cortical maps as the outcome of mathematically specified rules governing axonal growth and synapse formation in which neural activity plays a primary role. All of these models use Hebbian learning rules to achieve a mapping between cells in one or more input layers representing either cell classes in the retina(s) or the lateral geniculate nucleus (LGN) layers and connections with cells in a single output layer that represents the cortex. The interest of the models lies not so much in what can be computed with them, but in the fact that they are often able to replicate, sometimes in a very detailed way, the geometrical properties of different maps and their spatial relationships (Erwin et al. 1995; Swindale 1996, 2003; Goodhill 2007).

Detailed Description

Varieties of Cortical Map

In *retinotopic maps*, there is an orderly mapping of receptive field position in retinotopic coordinates (elevation and azimuth) in a brain region, as a result of topographically ordered connections between retinal ganglion cells and target structures. Such maps possess local order (neighboring retinal neurons tend to project to neighboring regions in the target structure) and global order, i.e., iso-elevation and iso-azimuthal contours have a predictable and consistent layout in the target structure. Retinotopic maps occur in the optic tectum in lower vertebrates such as frogs and fish and in the superior colliculus, LGN, and visual cortical areas of mammals. The rules governing the formation of maps in the optic tectum of frogs and fish, and their responses to experimental manipulations such as removing parts of the retina and/or the tectum, were among the first to be studied experimentally and to be modeled mathematically (Goodhill and Xu 2005; Goodhill 2007; Eglén and Gjorgjieva 2009). Much of this work can be applied to the development of maps in LGN and cortex as well.

Ocular Dominance Maps

When the visual fields of the two eyes overlap substantially, as they do in carnivores and most primates, the retinotopic maps also overlap, i.e., cells in the target structures will have receptive fields that are in approximately the same location in visual space. In such cases, the relative strength of the inputs from the two eyes, a property termed ocular dominance, is often found to vary systematically with position across the map, allowing it to be subdivided into interdigitating regions referred to as ocular dominance columns (Hubel and Wiesel 1977). The layout of the columns is generally periodic with a spacing in the range 0.8–2.0 mm depending on species. In old-world primates (such as macaque monkeys), the morphology is branching stripes (Fig. 1a), whereas in cats and ferrets, there is a less ordered pattern of elongated blobs and patches (Fig. 1b). Ocular dominance columns are not found in all species. They may be variably present in the visual cortex of new-world monkeys (Adams and Horton 2003) and are largely absent in the visual cortices of mice and rats which have only a very small binocular visual field (Hübener et al. 2008).

Orientation Maps

The majority of neurons in the primary visual cortex of all species that have been examined show orientation selectivity, i.e., the neuron will respond selectively to the orientation of a bar or edge flashed in, or moved across, the receptive field. The response is typically a bell-shaped function of stimulus orientation with a width in the range of 20–60° at half height and a peak that defines the cell’s preferred orientation. In carnivores and primates, preferred orientation has a columnar organization and varies smoothly and systematically with tangential position (Fig. 1c). As with ocular dominance columns, the periodicity is generally in the range 0.8–2.0 mm. However, when ocular dominance and orientation maps are simultaneously present in a visual cortical area, which is often the case, the periodicities are usually different. Because orientation is, by definition, a property that is cyclic in the range 0– π , it is often convenient to

Cortical Maps, Activity-Dependent Development,

Fig. 1 Ocular dominance column arrangements observed in macaque monkey visual cortex (**a**) and area 17 of cat visual cortex (**b**). *White areas* are regions of cortex labeled by injection of radioactive tracer into one eye. (**c**) Layout of orientation preference in area 17 of cat visual cortex. Singularities (*pinwheels*) are identifiable as points where many *color boundaries* intersect. (**d**) Layout of domains

of ocular dominance (outlined by *upper layer of black lines*), spatial frequency (*lowest layer*), and orientation (*colored lines, middle layer*). Singularities in this panel are identifiable as points where *colored lines* meet (Panel **a** is adapted from Hubel and Wiesel (1977); **b** is adapted from LeVay et al. (1978). **c** is from Hübener et al. (1997). Figure **d** was kindly supplied to the author by M. Hübener)

represent it as an angle-doubled complex number $z = ae^{i2\theta}$, where θ is the orientation and the length a of the vector represents response strength or tuning sharpness, or some combination of the two. Singularities (more commonly referred to as “pinwheels”) occur frequently in orientation maps (Fig. 1c, d). Mathematically these correspond to positions where $z = 0$ which will happen at locations where zero crossings in the real and imaginary components of z intersect (Swindale 1982). For most types of periodic layout of z , this will be a frequent occurrence (Wolf and Geisel 1998). Singularities can be classified by sign, where positive sign means that orientations rotate in a clockwise direction if a circular path enclosing a singularity is traversed in a clockwise direction, while negative sign means that orientations rotate in an anticlockwise direction for clockwise motion around the circuit. Positive and negative singularities are

found in approximately equal numbers in visual cortex maps (Obermayer and Blasdel 1997).

Direction Preference

In addition to selectivity for orientation, many visual cortical neurons give different responses to the two possible directions of motion of a long edge. This can range from the equal responses to both directions to no response at all in the so-called null direction, with the responses of most neurons falling between these two extremes. Direction preference is represented continuously in cat and ferret primary visual cortex with the topological consequence that lines, across which direction preference reverses, extend between and connect pairs of orientation singularities of opposite sign (Swindale et al. 1987). This arrangement has been confirmed experimentally (Swindale et al. 1987; Shmuel and Grinvald 1996; Weliky et al. 1996).

Spatial Frequency Maps

As an alternative to bars and edges, many experimenters have used moving sine wave gratings to study the responses of visual cortex neurons. Since the Fourier transform of an extended sine wave grating is a point in a 2D spatial frequency space (and a moving grating is a point in a 3D spatiotemporal frequency space), such stimuli allow the use of linear systems theory to characterize neuronal responses in space and time. Experimentally, it is found that the majority of primary visual cortex neurons will respond with an elevated, or modulated, firing rate to a moving grating stimulus, with the magnitude of the response varying with the orientation, direction of motion, and spatial frequency of the grating. Cells are also tuned for spatial frequency, with the position of the peak defining the preferred spatial frequency of the cell and the range defining a bandwidth (De Valois and De Valois 1990).

In a 2D space whose coordinates are horizontal frequency on the x -axis and vertical frequency on the y -axis (or equivalently in coordinates, spatial frequency = r and orientation = θ), tuning is typically an approximately Gaussian-shaped region centered on a preferred orientation and spatial frequency (De Valois and De Valois 1990). Transformed back into visual space, such a tuning function corresponds to a Gabor function. This can be explained in the following way: a Gaussian blob in spatial frequency space can be represented as a delta function positioned at the preferred (r , θ) value convolved with a 2D Gaussian. In spatial coordinates, this corresponds to the Fourier transform of a delta function, which equals a sine wave grating, multiplied by the Fourier transform of a 2D Gaussian, which is another Gaussian function. The resulting function turns out to be an excellent description of the spatial receptive field profile of many visual cortex neurons (Ringach 2002). Bandwidths for most visual cortical neurons are about 1–2 octaves, while within a single cortical area (e.g., area 17 of the cat), preferred spatial frequency can vary from cell to cell over a range of about 2–3 (Movshon et al. 1978; Born and Tootell 1991). Experiments in cats, monkeys, and ferrets have shown that preferred spatial frequency varies

periodically with position, with an overall layout that is independent of, but geometrically similar to, that of ocular dominance (Hübener et al. 1997; Issa et al. 2000; Yu et al. 2005; Nauhaus et al. 2012).

Additional Maps

Maps of retinal position, ocular dominance, orientation, direction of motion, and spatial frequency are all simultaneously present in area 17 of the cat (Fig. 1d) and ferret. Area V1 in macaque monkeys also contains a retinotopic map plus maps of ocular dominance, orientation, and spatial frequency. Additional maps are either known or very likely to be present. For example, there is an ordered sensitivity to stereoscopic disparity in cat area 18 (Kara and Boyd 2009), and several investigators have reported maps for color preference in macaque V1 (e.g., Lu and Roe 2008). How many different features may simultaneously be represented in maps in a single cortical area is currently unknown.

Rats, Mice, and Squirrels

It is worth noting specifically that the visual cortices of these animals have retinotopic maps but that the maps for preferred orientation and ocular dominance appear to be random, in both tangential and vertical (columnar) directions (Van Hooser et al. 2005; Ohki et al. 2005; Bonin et al. 2011). This is a violation of the principle of columnar organization and shows that it does not have always to be present. This might suggest that orientation and ocular dominance columns are adaptive features that arose in more recently evolved mammals with larger (and perhaps better) cortices. However, both rats and mice have well-developed visual abilities, and squirrels in particular have good visual abilities so it is hard to avoid the conclusion that columns are not essential features of a working cortex.

Maps in Other Cortical Areas

The bulk of our knowledge of possible forms of cortical map organization comes from studies of visual cortical areas. Maps are present in other

sensory areas (Mountcastle 1998; Inan and Crair 2007), but it is not clear if multiple features are overlaid in them with comparable complexity to visual cortex. Auditory cortex contains an ordered one-dimensional map of frequency, i.e., preferred auditory frequency is constant along one axis but varies, approximately as an exponential function of distance, along the orthogonal axis. There is evidence that other auditory response properties, such as envelope periodicity, may be mapped along the orthogonal dimension (Langner and Ochse 2006). It has long been known that somatosensory cortex has an ordered map of the body surface: early studies of this area showed that in addition to the map of the body surface (analogous to the retinotopic map), there were local subdivisions into regions which received input from different classes of sensory receptor, e.g., superficial and deep. These representations were found to be columnar, and studies showing it, done in the late 1950s, were among the first to demonstrate columnar organization (Mountcastle 1998). Taste has recently been shown to have an ordered representation in mouse gustatory cortex where there are small ($\sim 200\text{--}400\text{ }\mu\text{m}$ diameter) patches of cells, about 1–2 mm apart, that respond selectively to either bitter, salty, sweet, or umami tastants, each of which has a correspondingly specialized receptor in the taste buds (Chen et al. 2011).

Development of Cortical Maps

There is a long-standing debate about the extent to which human knowledge is innate or acquired through learning. In the narrower context of cortical maps, the debate likewise centers on the extent to which map development is the outcome of molecularly guided (innate, genetic, nature) or neural activity-dependent (environmental, learning based, nurture) cues. Although it is frequently pointed out that there can be complex interactions between genes and the environment, the nature-nurture dimension continues to be a useful one along which to characterize models and research findings. Initial research, begun in the 1960s, showed that cortical maps develop early in life

and that their structure can be altered by exposure, or lack of exposure, to specific stimuli during and after the period of map development. These findings inspired the development of various classes of computational neuroscience model that sought to explain cortical map development as the outcome of a self-organizing, activity-dependent process in which neural activity plays a critical role. However, it is now known that in the superior colliculus and optic tectum of lower vertebrates, retinotopic maps develop under the influence of molecular guidance cues (McLaughlin and O'Leary 2005) and it is highly likely that retinotopic and somatotopic maps in the cerebral cortex do so as well (Rakic et al. 2009; Cang et al. 2005; Inan and Crair 2007). Models based on correlated neural activity and Hebbian learning however remain the best candidates for explaining the refinement of retinotopic maps in the cortex (Huberman et al. 2008) as well as for the development of orientation and direction preference maps (White and Fitzpatrick 2007).

Sequence of Visual Cortex Map Development

While the timing of developmental events measured in days from conception varies considerably in different species, the general order is similar (Fig. 2; Workman et al. 2013). Retinal ganglion cells are generated very early in the sequence, but the retina is unlikely to be responsive to patterned light stimuli until shortly before the time of eye opening, at which point cells in both the LGN and cortex have finished dividing and migrating and LGN axons have already made synaptic connections in layer IV of the cortex. Visual responsiveness is likely to depend not just on the presence of rods and cones but also on the maturation of the bipolar neurons which link rods and cones to ganglion cells, and this happens relatively late in the sequence. Prior to this, and beginning from the time that retinal ganglion cells have reached the LGN, retinal ganglion cells fire coordinated bursts of action potentials that move in a wavelike fashion across the retina, outwards from an originating center (Wong 1999; Warland et al. 2006).

Cortical Maps, Activity-Dependent Development, Fig. 2 Timeline of development of the retina, LGN, and visual cortex maps in mouse, cat, ferret, and macaque monkey. Note that while the actual timing of events differs substantially in the different species, the overall order is similar in all of them. Several qualifications apply to the figure (discussed in the text): there is still debate over the

timing of ocular dominance column development; the mouse does not possess maps of ocular dominance, orientation, or direction preference, nor does the macaque have a direction preference map; the diagram should not be relied upon for exact timing details given that it is a synthesis across several species (Layout taken from Huberman et al. 2008; data from Workman et al. (2013))

(Stages I, II, and III differ in terms of cell type and transmitters and will not be discussed here.) The centers and directions of wavefront motion are seemingly random but with a refractory behavior so that cells that have fired in a burst are unlikely to participate in another one for some time. Such refractory areas often cause propagating waves to die out. The retinal waves continue throughout the period when the LGN layers are segregating and during the period when the LGN axons are innervating layer IV of the cortex. Interference with the waves has been shown to prevent segregation of LGN layers and to reduce the refinement of the retinotopic maps in the cortex (Torborg and Feller 2005; Firth et al. 2005; Huberman et al. 2008). As Fig. 2 shows, the timing of birth relative to development varies greatly in different species. Mice and ferrets are born relatively immature, before the retina is functional and before layers in the LGN and cortex have fully formed. Cats are born shortly before the retina is mature and about a week before the eyes open. Macaque monkeys are born very much later in the sequence with the eyes opening in utero about 6 weeks before birth. As light may well penetrate into the uterus,

the possibility of intrauterine visual stimulation exists, and this might also explain why the eyes would open before birth. However, the extent to which vision can occur in utero remains unknown.

Following birth, the trajectory of visual development is species dependent. In macaque monkeys, born much later relative to developmental milestones than other species, ocular dominance columns are present at birth (Horton and Hocking 1996), while orientation maps have been reported very soon afterwards (Wiesel and Hubel 1974). Ocular dominance and orientation maps begin to develop in cats about a week after eye opening and are adultlike 2–3 weeks later. Orientation maps start to develop in ferrets at the time of eye opening, followed about a week later by direction preference maps. Ocular dominance columns have been reported to be present prenatally in the ferret as well as in ferrets in which both eyes were removed (Katz and Crowley 2002). This observation, plus the recent discovery of a molecular marker for ocular dominance (Tomita et al. 2013), suggests that neural activity might not play a significant role in the formation of ocular dominance columns. However, patterned spontaneous

activity may still be present in the LGN of blinded ferrets, and its role cannot be ruled out. Likewise, a role for retinal waves, or even for intrauterine visual stimulation, cannot be ruled out in the development of ocular dominance columns which are present at birth in monkeys. Although orientation maps normally develop in the presence of visually driven activity in cats and ferrets, the presence of the maps in animals that have been dark-reared, as well as in newborn monkeys, suggests that either neural activity is not involved or that retinal waves, together with patterned spontaneous LGN and cortical activity, are able to cause maps to form in the absence of visually driven input. The observation that blocking activity in ON-center retinal ganglion cells prevents the development of orientation maps (Chapman and Gödecke 2000) suggests that neural activity is involved however.

As noted above, mice do not have maps of ocular dominance or orientation, though individual cells have these properties which hence may arise through activity-dependent interactions.

Although the role played by patterned neural activity, whether spontaneous or visually driven, in the development of orientation and ocular dominance maps remains uncertain, there is no doubt that alterations in the patterns of visual input can cause modification of map structure. Monocular deprivation (closing one eye), if done shortly after birth, causes a loss of inputs from the deprived eye and a gain in the number and strength of inputs from the other eye (Hubel and Wiesel 1977). In cats and monkeys, there is a corresponding change in the widths of the ocular dominance columns with active geniculate inputs taking over cortical territory formerly innervated by the deprived eye. Monocular deprivation has little effect if performed outside of a critical period: in mice, this is within 5 weeks after birth, cats about 3 months and monkeys about 6 months. Manipulation of the distribution of oriented stimuli has been done by either placing young animals in a cylinder on which vertical lines are the only visible contour or by fitting cylindrical lenses to the eyes: these cause orientations not matching the axis of the cylinder to be blurred. Such manipulations have been found to bias the distribution of

orientation preferences and, correspondingly, the structure of orientation maps in cat visual cortex (Sengpiel and Kind 2002). The development of direction preference has also been shown to be prevented by rearing animals in stroboscopic light which abolishes motion cues (White and Fitzpatrick 2007).

Vector Representation of Map Parameters

As outlined above, the receptive fields of neurons in V1 can be parameterized along a variety of dimensions represented in maps (Fig. 1d). For example, in cat visual cortex, we might represent the list as follows: receptive field position (x, y), ocular dominance (d), preferred orientation (itself a vector, $\mathbf{z} = (a, b)$), and preferred spatial frequency (f). We might represent the list of properties measured for cells at a point, i , on the cortical surface, by the vector $\mathbf{v}_i = \{x_i, y_i, d_i, a_i, b_i, f_i\}$. The complete mapping can be conceptualized as the projection of the 2D cortical sheet into a higher-dimensional feature space $\mathbf{S}$. This construction relies on a number of assumptions. Firstly, the representation of the cortex as a 2D sheet is based on the hypothesis of columnar organization. This appears generally to be true although exceptions to it have been claimed. Second, it should be noted that the values of x_i, y_i , etc. are the best values of response functions that are often Gaussian, or approximately Gaussian, in shape; hence, associating a point in the cortex with a single position in $\mathbf{S}$ is an oversimplification. Instead it would be more correct to think of positions in the cortex each populating $\mathbf{S}$ with spikes falling off in density from a central point. Thirdly, the representation of the receptive field as a point assumes that the best values x, y, d , etc. are independent of each other, e.g., that the preferred orientation is independent of the spatial frequency of the stimulus and its precise position. More formally this means (or assumes) that the response to a stimulus, $\mathbf{u}$, $R(\mathbf{u})$, can be expressed as the separable product of receptive field functions for each of the dimensions, i.e., that $R_i(\mathbf{u}) = F_1(x - x_i)F_2(y - y_i) \dots$ where $F()$ is typically a Gaussian. The assumption of

separability (see Yu et al. 2005 for discussion) and the consequent ability to describe cortical receptive fields as positions, or regions, in a feature space underlie many of the models that will be described in the following sections.

The Models

Linear Correlation-Based Models

All activity-based models of cortical map development assume that maps result from a combination of Hebbian synaptic plasticity, spatially structured activity in the input layer(s), and, necessarily, some form of structured local connectivity in the cortex. (If no local cortical connectivity was present, maps could not arise since the position of a cell in the cortical sheet would have no influence on the type of receptive field that emerged.) The class of correlation-based models discussed in this section further assume (a) that cortical neurons sum their inputs linearly, i.e., that the activity of a cortical unit is given by the dot product of a weight vector $\mathbf{w}$ and an input vector $\mathbf{u}$; (b) that weight changes take place slowly on the timescale of input activity variation, allowing the rate of weight change to be calculated as an average of activity; (c) that local connectivity in the cortex is described by a Mexican Hat function, typically a difference of Gaussians; and finally (d) that the models enforce competition between synapses in the form of normalization rules. These rules can enforce constancy of the sum of the inputs to a neuron; constancy of the sum of the outputs of an input neuron, or sometimes both. Normalization can be done by either multiplicatively scaling all the weights or subtracting from them. If subtractive normalization is done, additional rules have to be implemented to keep weights within realistic biological bounds, i.e., zero and some maximum value. Normalization constraints are usually imposed separately (i.e., following updates of the weight values at each computational step), while the main description of the model will take the form of equations describing the rate of weight change as a function of the weights, distance-dependent correlation functions in the input layers, and the cortical interaction function. However, normalization,

and the way in which it is done, is arguably as important as the rest of the model as this step is often the only one that allows weight values to decrease. This is obviously an essential element in developing response selectivity. Models that use the BCM learning rule, which explicitly includes a mechanism for decreasing weights as part of the learning rule (Dayan and Abbott 2001), are an exception to this.

The use of these assumptions is illustrated in a simplified model of ocular dominance column development presented by Dayan and Abbott (2001). This model is itself based on earlier models. In this setting (Fig. 3), two units with activities u_L and u_R connect, via sets of modifiable feedforward weights $\mathbf{w}_L$ and $\mathbf{w}_R$, to a single layer of cortical units with activities v_i , where i indexes position on the cortical surface. The cortical units are connected by a set of fixed recurrent (i.e., lateral) weights M_{i,i^*} with the property that the strength of the connection varies as a Mexican hat-shaped function of the distance $d = |i - i^*|$ between two positions i and i^* . The vector $\mathbf{u} = (u_L, u_R)$ represents the input activities, the matrix $\mathbf{W} = (\mathbf{w}_L, \mathbf{w}_R)$ represents the feedforward weights, $\mathbf{v}$ represents the activities of the cortical units, and $\mathbf{M}$ represents the connections between cortical units. A simple interpretation of Hebbian learning is that weights change in proportion to the time-

Cortical Maps, Activity-Dependent Development, Fig. 3 The setting for the ocular dominance column model described in the text

averaged product of the activities of the input (pre-) and output (post-) units, i.e., that

$$\tau_w \frac{dW}{dt} = \langle \mathbf{v} \mathbf{u}^T \rangle \quad (1)$$

where τ_w is a learning rate constant. To evaluate this, we first have to calculate the output activities, $\mathbf{v}$, which will depend on recurrent connections as well as the input activities and the connection weights. This can be simplified by finding the steady-state solution of the following recurrent model:

$$\tau_v \frac{dv}{dt} = -\mathbf{v} + \mathbf{W} \mathbf{u} + \mathbf{M} \mathbf{v} \quad (2)$$

which is given by

$$\mathbf{v} = \mathbf{W} \mathbf{u} + \mathbf{M} \mathbf{v}$$

This has the solution

$$\mathbf{v} = \mathbf{K} \mathbf{W} \mathbf{u} \quad (3)$$

where $\mathbf{K} = (\mathbf{I} - \mathbf{M})^{-1}$ and $\mathbf{I}$ is the identity matrix. Note that $\mathbf{K}$ can be regarded as a redefined cortical connection matrix which allows a one-step calculation of the cortical response to a given input vector as

$$v_i = \sum_{i^*=1}^{N_i} K_{i,i^*} (W_{R,i^*} u_R + W_{L,i^*} u_L).$$

Substituting Eq. 3 into Eq. 1 gives

$$\tau_w \frac{dW}{dt} = \mathbf{K} \mathbf{W} \langle \mathbf{u} \mathbf{u}^T \rangle = \mathbf{K} \mathbf{W} \mathbf{Q} \quad (4)$$

where $\mathbf{Q} = \langle \mathbf{u} \mathbf{u}^T \rangle$ is the input correlation matrix. For two inputs, this has the form

$$\begin{pmatrix} q_S & q_D \\ q_D & q_S \end{pmatrix}$$

where q_S is the within-eye correlation (for one unit, this is just the r.m.s firing rate) and q_D is the between-eye correlation. In general, we expect the firing patterns to be different in the two eyes, which guarantees that $q_S > q_D$.

Equation 4 can be solved for sum and difference terms of $\mathbf{w}_R$ and $\mathbf{w}_L$, i.e., by defining $\mathbf{w}_+ = \mathbf{w}_R + \mathbf{w}_L$ and $\mathbf{w}_- = \mathbf{w}_R - \mathbf{w}_L$. We then have

$$\tau_w \frac{d\mathbf{w}_-}{dt} = (q_S - q_D) \mathbf{K} \mathbf{W}_- \quad (5a)$$

and

$$\tau_w \frac{d\mathbf{w}_+}{dt} = (q_S + q_D) \mathbf{K} \mathbf{W}_+ \quad (5b)$$

Solutions to Eq. 5a for $q_S > q_D$ take the form of a sum of exponentially growing modes determined by the eigenvalues and eigenvectors of $\mathbf{K}$. The eigenvectors are the discrete Fourier components of K and hence are periodic functions of cortical distance $|i - i^*|$. The dominant, most rapidly growing mode will be the one with the largest amplitude (Fig. 4). Solutions to Eq. 5b represent even more rapidly growing modes; however, these represent an increase in the values of the summed weights from both eyes to each cortical cell. Application of normalization rules will ensure that $d\mathbf{w}_+/dt = 0$. Periodic fluctuations in the value of $\mathbf{w}_- = \mathbf{w}_R - \mathbf{w}_L$ can be identified with the reciprocal periodic fluctuations in ocular dominance observed in the real cortex.

A more elaborate version of the above model was presented by Miller et al. (1989). In this model, two input layers (rather than just two units), labeled R and L , project to a sheet of cortical units. Position in the input layers is given by α or β and position in the cortex is given by x or y (note that for 2D arrays these are all 2D position vectors, and not indices). Units in each input layer project to a small area of the output layer as defined by an arbor function $A(x - \alpha)$. $A = 1$ if the distance $|x - \alpha|$ is less than a fixed arbor radius and is zero elsewhere. This formulation enforces a rigid retinotopic mapping with a cortical point x having a receptive field centered at position $\alpha = x$ in the input layer. Connection strengths from the R input layer change according to

$$\begin{aligned} \frac{dw_R(x, \alpha, t)}{dt} = & \varepsilon A(x - \alpha) \sum_{y, \beta} K(x - y) \\ & [Q_{RR}(\alpha - \beta) w_R(y, \beta, t) + Q_{RL}(\alpha - \beta) w_L(y, \beta, t)] \end{aligned} \quad (6)$$

Cortical Maps, Activity-Dependent Development, Fig. 4 (a) A Mexican Hat (difference of Gaussians) lateral interaction function, K , showing the largest eigenvector (e) or (equivalently) the largest of its Fourier components

(dashed line). (b) The Fourier transform of the function, $\tilde{K}$, showing a maximum at a positive wavelength, k (From Dayan and Abbott 2001)

where ε is a constant determining the overall growth rate, K is the cortical interaction function, and the functions Q_{RR} and Q_{RL} describe the dependence of the auto- and cross-correlation functions of LGN activity with distance. Miller et al. assumed that the within-eye correlation functions were positive Gaussians, while the between-eye correlations were either zero or negative Gaussians. The equation for dw_L/dt is obtained by interchanging L and R in Eq. 6.

The behavior of this system is similar to that of Eq. 4 with reciprocal periodic fluctuations in the ocular dominance of the cortical receptive fields developing across the surface of the cortex. As with Eq. 4, the periodicity is predictable from the frequency for which the Fourier power spectrum of K has a maximum amplitude. Less predictably, the model (and others like it) generates spatial patterns of branching stripes and elongated blobs that closely resemble the biological patterns. The production of stripes from circularly symmetric interactions can be regarded as a success of the models although the reasons for it, and possible quantification of the morphology so that model outputs and biological data can be more closely compared, have received relatively little theoretical attention.

Equation 6 can be applied to the development of orientation preference. In this model, the two input layers represent ON- and OFF-center retinal inputs. Model parameters are adjusted so that segregation of inputs occurs on a small scale, within receptive fields, leading to alternating

bands of ON and OFF inputs to each cortical unit and hence resulting in orientation selectivity. Although neighboring cortical cells have similar orientation preferences (the result of the overlap in their receptive fields), the overall layout of orientation in this model is nonperiodic, which is at odds with real orientation maps. A combined model, with ON and OFF layers for each of the two eyes, giving four input layers, has also been presented as a model for the joint development of orientation and ocular dominance maps (Erwin and Miller 1998).

Competitive Hebbian Models

Equation 3 shows that the cortical response to an input vector is the product of the vector and the weight vector for the same point, filtered by the lateral cortical interaction function. The response is proportional to the match (or projection) of the input vector in the space of weights (which has as many dimensions as there are inputs to each cell) and the weights of that cortical unit. This satisfies the intuitive notion that the stimulus that matches the receptive field profile best will be the one that gives the largest response. If the stimulus does not match the weights exactly, Hebbian modification will have the effect of changing the weights so as to make that cortical point more responsive to the stimulus in future presentations. In weight space, this means that the weight vector moves towards the position of the stimulus in the same space. As shown in Eq. 4, the assumption of linear cortical responses allows the calculation of weight

changes to be based on time-averaged correlation functions rather than on a sequential presentation of many different input patterns. This speeds up simulations but does not allow the possible effects of nonlinearities in the cortical response to be taken into account. Kohonen (1997) took an alternative approach to simplifying the calculation of cortical activities by finding the cortical point, i^* , whose weight vector best matched the input vector. Weight values of this point, and, crucially, values of surrounding cortical points in a region defined by a neighborhood function, are then adjusted to make these points more responsive to the stimulus. The fact that only a single cortical point is chosen, no matter what the stimulus, makes the learning competitive and highly nonlinear. The model has been applied in two forms, a high-dimensional version and a low-dimensional version. The setting for the high-dimensional version is similar to the one above where one or more sheets of cells project to a cortical sheet. In this case however, lateral cortical connections are assumed rather than specified explicitly. The winning cortical location is found by calculating $v_i = \mathbf{w}_i \mathbf{u}$ for all cortical locations and finding the point, i^* , for which v_i is a maximum. Weights are then changed according to

$$\mathbf{w}_i(t+1) = \alpha(t)[\mathbf{w}_i(t) + \varepsilon h(i^*, i) \mathbf{u}(t)] \quad (7)$$

where α is a normalization constant chosen to keep the sum of the weight values (or the sum of the squares) constant for each cortical point, ε is a learning rate constant and $h(i^*, i)$ defines the cortical neighborhood function in terms of the distance between points i and i^* , and $\mathbf{u}(t)$ is the input presented at timestep t . The neighborhood function h is normally a Gaussian and for cortical simulations typically is a few hundred microns in width. In simulations employing this rule, static input patterns are presented one at a time and weights are updated at each step. Adaptive weight updating means that cortical units become selectively responsive to those inputs presented during training and lose their responsiveness to stimuli not presented. The cortical neighborhood function, which causes points near the winning one to become more responsive to the same stimulus,

irrespective of their weight values, enforces continuity in the representation of the those points in the stimulus space. Hence, the Kohonen algorithm performs a dimension-reducing, topology-preserving mapping of points in a high-dimensional input space onto a two-dimensional cortex.

In the low-dimensional version, stimuli are represented not as activity distributions in sheets of cells but as points in a reduced feature space whose dimensions are the receptive field parameters represented in the map. Weights in this formulation represent stimulus selectivities of the cortical units rather than single synapses. The learning rule for this version of the model is

$$\mathbf{w}_i(t+1) = \mathbf{w}_i(t) + \varepsilon[\mathbf{u}(t) - \mathbf{w}_i(t)]h(i^*, i) \quad (8)$$

Here, point i^* is defined as the one for which $|\mathbf{u} - \mathbf{w}|$ is a minimum, i.e., it is the cortical point that is closest (most responsive) to $\mathbf{u}$. At each step, learning has the effect of moving $\mathbf{w}_{i^*}$, and its cortical neighbors, closer to $\mathbf{u}$, the currently presented stimulus. For visual cortex maps, the dimensions of the feature space inhabited by $\mathbf{w}$ and $\mathbf{u}$ might be chosen to include retinotopic position (2 dimensions), ocular dominance (1), and orientation (2) to give a five-dimensional space, though other parameters such as spatial frequency or direction of motion might also be added. This rule has a simple geometrical interpretation. Points i index positions in the cortex which may typically be represented on a rectilinear or hexagonal lattice. The function $\mathbf{w}_i$ maps these points into the feature space; hence, one can imagine the cortex as a 2D lattice of points folded into the space. Points $\mathbf{u}$ in the space are chosen one at a time, according to a probability distribution $p(\mathbf{u})$, and for each, the cortical point that is closest is found. This point and its neighbors are moved towards the stimulus. This process is repeated (possibly for many thousands of stimuli) until a map has formed.

Both high- and low-dimensional forms of the Kohonen model have been used to model visual cortex map development (Erwin et al. 1995; Swindale 1996, 2003). The low-dimensional version has the advantage of being simple to

implement and it is relatively fast to compute map layouts for reasonably sized areas of cortex (e.g., a simulation involving five dimensions and 200×200 sized cortex corresponding to an area of about 4×4 mm might take a few hours or less to compute). Unlike the linear correlation-based model discussed above, a fixed retinotopy is not assumed, allowing investigations of possible relations between local magnification of the retinotopic map and the rates of change of other map parameters.

Piepenbrock and Obermayer (2000) introduced a model that bridges the extremes of linear and competitive cortical activation models. In this framework, cortical activation is produced by a softmax function:

$$V_i = \frac{\exp(\beta \mathbf{w}_i \mathbf{u})}{\sum_i \exp(\beta \mathbf{w}_i \mathbf{u})} \quad \left(\text{or} \quad V_i = \frac{(\mathbf{w}_i \mathbf{u})^\beta}{\sum_i (\mathbf{w}_i \mathbf{u})^\beta} \right) \quad (9)$$

In the limit of $\beta \rightarrow \infty$, the output is a delta function positioned at the largest value of v_i leading to the winner-take-all behavior of the Kohonen model. In the limit $\beta \rightarrow 0$, $v_i \rightarrow \mathbf{w}_i \mathbf{u}$ giving the linear noncompetitive learning model.

The Elastic Net Model

The low-dimensional version of the Kohonen mapping algorithm (Eq. 8) causes a 2D cortical sheet to project into a higher-dimensional feature space in such a way that the projection is (a) locally continuous (resulting from the neighborhood function) and (b) the sheet approximates the distribution of stimuli within the space. The elastic net algorithm, devised by Durbin and Willshaw (1987), achieves a similar end, but by different means. The term “elastic net” applies to a lattice of cortical points which can be conceived as an elastic net with adjacent nodes on a square lattice connected by elastic. Under the influence of the elastic forces, the net would collapse to a point. However, stimuli – fixed points in the feature space – exert attractive forces on the net, which get stronger the shorter the distance between the stimulus and the cortical point. The algorithm calculates a stable configuration of the net

(i.e., cortical receptive field values) for a given, fixed set of stimuli distributed in the space in some manner. The learning rule is

$$\mathbf{w}_i(t+1) = \mathbf{w}_i(t) + \alpha \sum_j F_{ij} \cdot (\mathbf{v}_j - \mathbf{w}_i) + \beta \sigma \sum_{k \in N_i} (\mathbf{w}_k - \mathbf{w}_i) \quad (10)$$

where α and β are rate constants, and the summation in the second term is over the nearest neighbors k of point i . The “force” F_{ij} exerted by stimulus j on cortical point i is a Gaussian function of the distance between $\mathbf{w}_i$ and $\mathbf{v}_j$ (i.e., the response, assuming Gaussian receptive fields) normalized by the sum of the responses from all other cortical units, i.e.,

$$F_{ij} = \frac{\exp(-|\mathbf{v}_j - \mathbf{w}_i|^2 / 2\sigma^2)}{\sum_p \exp(-|\mathbf{v}_j - \mathbf{w}_p|^2 / 2\sigma^2)}. \quad (11)$$

It should be noted that this formulation results in the elastic net algorithm being nonlocal, i.e., it is necessary to sum over every point in the cortex to determine the learning rate of any particular cortical point. This might be criticized as unbiological. However, normalization ensures that stimuli that are far away from any cortical point do not get ignored and exert forces that are as large as those exerted by stimuli that are closer to cortical units. Parameter σ scales the distance over which stimuli exert attractive forces. Initially this distance may be large, and it is typically reduced in size (a process referred to as “simulated annealing”) in order to make individual cortical points approach specific stimuli.

The expression for weight change can be integrated to yield an energy function:

$$E = -\alpha \sigma \sum_i \log \sum_j \exp(-|\mathbf{v}_i - \mathbf{w}_j|^2 / 2\sigma^2) + \frac{1}{2} \beta \sigma \sum_j |\mathbf{w}_j - \mathbf{w}_{j+1}|^2 \quad (12)$$

By definition, this has the property that $\Delta \mathbf{w}_j = -\partial E / \partial \mathbf{w}_j$. At each iteration, $\partial E (= -\Delta \mathbf{w}_j \partial \mathbf{w}_j)$ is guaranteed to be negative provided that $\Delta \mathbf{w}_j$ is

small enough that its sign is always the same as ∂w_j . Hence, the learning rule will always lead to a decrease in the value of E . The expression for E has an interesting interpretation. The term $\exp(-|v_i - w_j|^2/2\sigma^2)$ can be interpreted as the response of cortical point j to a stimulus i , a Gaussian function of the distance between the stimulus v_i , and the receptive field center, w_j . The summation over cortical points indexed by j thus measures the total response of the cortex to a given stimulus (assuming Gaussian tuning functions). The log of this term is then summed over i , that is, over all the stimuli. As in an entropy measure, the magnitude of this sum will be largest, and hence the contribution to E most negative, when the distribution of responses over the stimuli (for a fixed total sum) is flat. Hence, this part of E measures what has elsewhere been termed “coverage uniformity” – the idea being that the cortical maps ought to be organized so that the net response to a stimulus should be invariant with respect to parameters such as retinal location, eye of stimulation, and orientation (Swindale 1996). The second term in Eq. 12 measures the sum of all the distances between the net points as projected into the feature space. Hence, it is a measure of how smooth the map is. It can be minimized by contracting the net to a point, but this will clearly lead to extremely unequal responses to different stimuli. Depending on the ratio between parameters α and β , maps that minimize E will represent a trade-off between coverage uniformity and local smoothness. This fact, plus the finding that maps generated with the elastic net algorithm (Fig. 5) resemble real visual cortex maps (for a range of values of α and β), suggests that cortical maps also represent a compromise between coverage uniformity and local smoothness. Local smoothness is not in itself a functional constraint, but it may be related to axonal connection lengths, if it is assumed that the total number of connections between cell pairs increases with the similarity of their receptive fields. Since axons take up a significant proportion of the volume of cortex, arranging a map so that cells with similar receptive fields are as close to each other as possible (subject to the conflicting constraint of coverage uniformity) will reduce the volume of cortex.

Cortical Maps, Activity-Dependent Development, Fig. 5 Cortical map model produced by the elastic net algorithm. *Black lines (lowest layer)* represent ocular dominance boundaries, *green lines (top layer)* represent spatial frequency domain boundaries, *thin blue- and red-colored lines (middle layer)* show iso-orientation domain boundaries, and *thick red lines* mark lines across which direction preference reverses. These lines begin and end in orientation singularities. Note the frequent orthogonal intersections of all types of boundary. This figure can be compared with the experimental data shown in Fig. 1d (From Carreira-Perpinán et al. 2005)

Models Based on Plasticity of Lateral Intracortical Connections

The LISSOM (Laterally Interconnected Synergetically Self-Organizing Map) model was devised initially by Miikkulainen and has since been extended and explored by him and his colleagues (Miikkulainen et al. 2005). LISSOM differs from most other cortical map models by having modifiable short range excitatory and longer-range inhibitory lateral connections in the cortex. The model exists in various forms but a standard implementation has a single layer of retinal units, representing a visual input, connecting to layers of ON- and OFF-center LGN units via fixed, topographically ordered weights. These units project to a single layer of laterally interconnected cortical units. LGN and cortical units compute their responses as the dot product of the input and weight vectors with a

sigmoidal activation function that constrains activities to lie between 0 and 1. Cortical activities are computed by iterating an activation equation which includes the lateral inputs. Responses are calculated to individual stimulus patterns and then the LGN to cortex weights and the lateral weights are modified according the product of pre- and postsynaptic activities. Following this, weights are normalized divisively.

Much of the interest of the LISSOM model comes from studying its behavior when trained with structured visual inputs (e.g., natural images) which have higher-order correlations that are ignored or absent in standard correlation models. LISSOM incorporates Hebbian strengthening of inhibitory synapses in proportion to the product of pre- and postsynaptic activities. This rule was initially proposed by Barlow and Földiák (1989) and was termed “anti-Hebbian” learning by them. It has the effect of decorrelating cortical responses to correlated input patterns and leads to a more sparse representation of visual images. It is likely that the LISSOM learning rule will lead to the development of receptive fields that are the independent components of the input images which, as shown elsewhere for natural images, are oriented Gabor-like filters closely resembling the receptive fields of simple cells (Olshausen and Field 1996; Hyvärinen and Hoyer 2001).

The assumptions of LISSOM have mixed experimental support: there is evidence for Hebbian plasticity of inhibitory cortical synapses (Gaiarsa and Ben-Ari 2006); however, experimental results show that longer-range (1–5 mm) lateral cortical connections (which are the ones that would seem most likely to be involved in decorrelating images) are excitatory while inhibitory connections travel shorter distances (Gilbert 1992). However, these shorter range connections might still play a role in decorrelating cortical responses. The fact that much cortical map development takes place in the absence of visually driven activity (and hence interesting higher-order structure) suggests that natural images do not play a role in the formation of simple cell receptive fields so that the types of developmental plasticity that LISSOM would seem best at

modeling are perhaps those that occur at relatively late stages of map development.

Overview of “Simple” Models of Map Development

The models outlined above are variably, sometimes highly, simplified abstractions of cortical map development. The advantages of such simplification are many. They make simulations computationally feasible and they allow model behavior to be understood in terms of functional properties, such as wirelength minimization, that are likely to have been important constraints on the evolution of developmental mechanisms. Because the number of parameters is often small, empirical studies of the effects of changing them is much easier. Mathematical simplicity also allows for the possibility of making predictions based on analysis rather than computer simulation and for discovering relationships between different kinds of models. This form of understanding has allowed many of the models to be usefully applied to problems other than simulating cortical map development. For example, the elastic net algorithm can produce solutions to the traveling salesman problem, while the Kohonen algorithm, initially inspired by the problem of cortical map development, has arguably had more applications in areas outside developmental neuroscience than within it (Kohonen 1997). Many forms of connection between Kohonen, elastic net, and correlation-based models have been drawn, the upshot being that all of the models can be shown to perform gradient descent, at least approximately, on a function that represents a trade-off between the conflicting constraints of coverage uniformity and local smoothness (Goodhill and Sejnowski 1997).

“Realistic” Models of Cortical Map Development

These strengths notwithstanding, abstract models can be criticized because of the many details they leave out. These details are likely to play roles in

development that will be best understood in the context of a computational model. Real cortical development is the result of the guided outgrowth, branching, and retraction of axons, together with the reciprocal extension and retraction of dendrites and the coordinated formation and loss of synaptic connections between the two. The field of research studying these processes is large and rapidly progressing and a time should come when the vast majority of the genetic and molecular mechanisms underlying these processes will have been characterized. Arguably, such a reductionist description will not be complete until it can be shown that larger-scale phenomena can be correctly predicted as the outcome of lower-level molecular interactions. This will almost certainly necessitate highly detailed, though also highly constrained, computer modeling of biochemical, cellular, and multicellular interactions and environmental stimulation. A major value of such models may lie in their ability to predict a phenotype given one or more genetic mutations known to play a role in mental illness. Perhaps in anticipation of such a scenario (which may be decades away), several recent models of visual system development have simulated the behaviors of growing axons, incorporating branching and retraction rules, the effect of molecular markers (Ephrin and eph receptor gradients), neuronal growth factors, synaptic plasticity rules, and detailed simulations of retinal input activity patterns (Yates et al. 2004; Godfrey et al. 2009; Grimbert and Cang 2012). While they are capable of correctly replicating known macroscopic developmental features as well as a variety of experimental results, these models currently have the disadvantage that computations are slow to complete and this, plus their complexity, makes it very hard to assess and predict the effects of changes in rules and parameter values on model output. This situation is likely to change as computers get faster and as the models get more tightly constrained by biological findings.

Experimental Tests of Model Predictions

For the class of “simple” model discussed in this article, the interplay between experiment and

theory has been vigorous and interesting. Despite their success however, the assumptions on which most, if not all, of the models are based remain unproved. The most common of these is the postulate of radially symmetric Mexican Hat connectivity in the cortex. Although this exists in the retina, there is no evidence for a greater spread of inhibitory connections relative to the spread of excitatory connections in the cortex. The connections that go furthest in the visual cortex are excitatory and have a patchy, asymmetric spread which is at odds with radial symmetry (Gilbert 1992). It remains possible that there is a second class of lateral excitatory connections which are extremely local ($<250\ \mu\text{m}$), and these, combined with the known inhibitory ones, might provide the desired connectivity. However, this remains a speculation. Neither the Kohonen nor elastic net models explicitly require Mexican Hat connectivity; however, the elastic net model has a normalization term that requires summing over the entire cortex, and since no known intracortical connections span such distances, it is not clear how this might be implemented biologically. The winner-take-all mechanism of Kohonen likewise requires a biologically unfeasible comparison across the entire cortex (as does the related model of Piepenbrock and Obermayer). In these cases, more plausible models might be constructed that avoided global comparisons.

By definition, all the models discussed here rely (implicitly if not explicitly) on the presence of local correlations in the patterns of neural activity in the inputs to the cortex which come primarily from the LGN. Here, the experimental evidence is more supportive. Retinal wave activity has now been fairly thoroughly characterized. The waves introduce correlations between ganglion cell activity that fall off approximately as Gaussian functions with distance (Wong et al. 1993; Stafford et al. 2009). The wave activity is transmitted through the LGN to the cortex (Ackman et al. 2012) and hence is capable of influencing cortical development in the manner proposed by correlation-based models. The cross-eye correlations for spontaneous activity would be expected to be zero although Ackman

et al.'s data suggest the possibility of cross-eye coordination which has so far been assumed not to exist. There is a considerable body of evidence showing that blocking or altering patterns of spontaneous activity in the retina interferes with cortical map development. Examples of this include the finding that blocking spontaneous retinal activity prevents refinement of retinotopic maps in mouse visual cortex and in ferrets disrupts ocular dominance column formation, though it does not completely abolish it (Huberman et al. 2008). This evidence that the initial stages of ocular dominance column formation are activity dependent has to be set against the finding that ocular dominance columns could be observed in ferrets almost simultaneously with the initial innervation of layer IV by LGN afferents, as well as in ferrets whose eyes had been removed (Katz and Crowley 2002). The implication that molecular cues, rather than neural activity, may be involved in segregation is also supported by the recent finding of a molecular marker for ocular dominance columns (Tomita et al. 2013). Whether the molecular markers play a primary or a passive role in segregation, or interact with activity-dependent mechanisms, remains to be determined however.

The role of correlated activity in the development of orientation selectivity is also unclear, mostly because fewer experiments have been done to study the question. Blocking activity in retinal ON-center ganglion cells in ferret retinas prevents the development of orientation selectivity (Chapman and Gödecke 2000). This finding, plus evidence that differences in the spontaneous firing patterns of ON- and OFF-center ganglion cells emerge about halfway during the period of retinal wave activity (Kerschensteiner and Wong 2008), supports the ON-OFF competition-based model of Miller (1994). However, the model has the weakness that it does not produce realistic periodic patterns of orientation preference while the parameter regime required for simultaneous emergence of both ocular dominance and orientation preference is narrow (Erwin and Miller 1998).

In spite of their relative lack of empirical support, many of the models, especially those based

on Kohonen and elastic net algorithms, have been spectacularly successful in reproducing and in several cases correctly predicting experimental observations. Among these successes can be counted the visual resemblance of the layouts of ocular dominance and orientation domains produced by the majority of the models and those observed experimentally. The presence of half-rotation singularities in the orientation maps, their overall density, their tendency to lie in the centers of ocular dominance stripes, and the statistics of the distributions of positive and negative singularities are all correctly reproduced (Erwin et al. 1995; Swindale 1996, 2003; Goodhill 2007). The Kohonen and elastic net models all produce maps in which gradients of change in specific maps (e.g., ocular dominance or spatial frequency) tend to be orthogonal to each other, most likely because of the algorithms' optimization of coverage (Durbin and Mitchison 1990; Swindale 2000; Carreira-Perpinán et al. 2005). Orthogonal gradient relationships have been observed experimentally between orientation and ocular dominance, ocular dominance and spatial frequency, ocular dominance and disparity, and spatial frequency and orientation (Hübener et al. 1997; Yu et al. 2005; Nauhaus et al. 2012). A prediction that reducing the number of feature dimensions present in a map should lead to an increase in the spacing of the remaining features (Swindale 2004; Carreira-Perpinán et al. 2005) was also tested and confirmed (Farley et al. 2007).

Final Words

"Nothing in biology makes sense except in the light of evolution" and the models presented here arguably only make sense because they show how activity-based Hebbian learning rules can optimize a variety of properties likely to have been subject to selection pressure. These include efficiency of information representation as reflected by coverage uniformity and sparseness of coding: good coverage is needed to represent the information in images faithfully, while sparse coding minimizes energy use (Vincent et al. 2005).

Minimizing wirelength leads to a reduction in brain volume and faster processing (Chklovskii and Koulakov 2004). It may be pointed out however that these performance optimizations offer little insight into the kinds of cognitive learning that take place in the cortex after birth. At the other end of the nature-nurture debate, the forms of topographic connectivity that molecular gradients are known to generate seem a long way removed from the kinds of connectivity that would be needed to establish such complex things as universal rules of grammar or neonatal abilities such as speech and face recognition (Marcus 2004). A considerable amount of work remains to be done to show how innate, genetically based mechanisms can lead to the establishment of neural structures on which Hebbian (or other) correlation-based learning rules can operate to produce the behaviors that are critical to the functions of the cortex.

Cortical Maps, Intrinsic Processes

Geoffrey J. Goodhill

Queensland Brain Institute and School of Mathematics and Physics, University of Queensland, St Lucia, QLD, Australia

Definition

A cortical map is a neural representation of an input space (e.g., the two dimensions of visual space and/or features such as orientation preference and ocular dominance) such that similar features in the input space are represented by neurons which are nearby in the cortex.

Detailed Description

A common way in which axonal projections connect areas in the brain is via topographic maps. Although there is no precise mathematical definition of this term, roughly speaking it means that neurons that are physically nearby in the input region, or alternatively neurons that have similar functional properties, map to neurons that are nearby in the target region. The formation of these maps during neural development depends on both intrinsic (molecularly guided) and extrinsic (activity-dependent) cues and has served as a paradigm model for how such cues guide brain development more generally. Activity-dependent effects on map development are the subject of a separate chapter; here we consider the role of intrinsic cues.

The formation of topographic maps has been particularly well studied in the visual system. A paradigmatic example is the projection from the retina to the tectum (frogs, fish, birds)/superior colliculus (mammals). To explain how such maps develop, Sperry (1963) defined the key theoretical idea of chemospecificity: a process of matching of chemically defined labels between the input and target structures. One particularly elegant form of

this idea is that the input structure contains a spatial concentration gradient of a receptor, which is matched to a spatial concentration gradient of a ligand in the target structure. In the 1990s, this prediction was experimentally confirmed via the discovery of gradients of Eph receptors in the retina, and their ligands the ephrins in the tectum/superior colliculus (Fig. 1; McLaughlin and O'Leary 2005).

Numerous experimental manipulations to the retinotectal system have provided a rich dataset of mapping outcomes following either molecular disruptions of the gradients (Lemke and Reber 2005; Huberman et al. 2008; Cang and Feldheim 2013) or surgical disruptions of the input or target structures (such as removing or rotating parts of the eye and/or the tectum) (Udin and Fawcett 1988; Goodhill and Richards 1999). Together these experiments provide many constraints for theories of map formation.

Early models in the 1970s and 1980s addressed basic principles for how gradient matching could establish maps in general and how versions of these principles could reproduce many of the surgical manipulation experiments in the retinotectal system (Willshaw and Price 2003; Goodhill and Xu 2005). These principles include competition for target space and other types of fiber-fiber interactions in addition to gradient matching. In the 1990s, models were proposed based closely on the

properties of the newly discovered Eph and ephrin gradients, though often without also considering the surgical manipulation data (Goodhill and Richards 1999). More recent models have been particularly concerned with data from recent gene disruption experiments, where, for instance, Eph levels are changed in only a subset of retinal cells or where a much smaller than normal number of retinal cells send axons to the tectum (Simpson et al. 2009). The mathematical principles underlying all these models are quite diverse, though many are based on the idea of optimizing an energy function for the map. Although no one modeling approach has yet become canonical, together these models have helped to clarify the relative roles and importance of the different biological mechanisms (most notably gradients, competition, and fiber-fiber interactions) involved in map formation.

Intrinsic processes of map development in the cortex have been far less studied than for retinotectal maps; however, there is recent evidence that similar principles of matching between Eph and ephrin gradients also guide their initial formation (Huberman et al. 2008). An intriguing question is whether the formation of functional maps in the cortex, such as ocular dominance and orientation maps in primary visual cortex, could also be partly controlled by intrinsic processes. Recent data has found molecular differences between regions of very young cat visual cortex which are reminiscent of the patterns of ocular dominance columns that subsequently develop, though a causative link has yet to be established. Similarly, clonally related neurons (those arising from a single progenitor cell) in rat visual cortex have been found to have orientation preferences that are more similar than non-clonally related neurons, challenging purely activity-dependent accounts for the development of orientation preference.

In summary, models up to now have played a critical role in demonstrating the effectiveness (or otherwise) of principles for how map development could occur and dissecting how the precise details of particular biological processes affect map structure. However, the constant flow of new data continues to provide new questions and challenges, which will provide inspiration for modeling work in this area for some time to come.

Cortical Maps, Intrinsic Processes, Fig. 1 Gradient matching in the retinotectal system. Eph receptors are expressed in an increasing nasal (N) to temporal (T) gradient in the retina, while ephrin ligands are expressed in an increasing rostral (R) to caudal (C) gradient in the tectum. The Eph-ephrin interaction is repulsive, so that regions of retina with high levels of Eph receptor map to regions of tectum with low levels of ephrin ligand, and vice versa

Definition

Neuromotor prostheses or, more commonly referred to as brain-machine interfaces (BMIs) or brain-computer interfaces (BCIs), refer to systems controlling prosthetic devices via an interface with ensembles of the neurons often from the cortex. Electrical potentials emanating from neurons in the vicinity of an electrode interface are decoded to extract useful control signals for external devices, typically an artificial limb or a robot. Nonelectric potentials such as the metabolic signals are also being used in some BMIs.

Detailed Description

Cortically controlled BMIs utilize voluntary modulations of cortical neurons in controlling an external prosthetic device. The system-level architecture of a BMI setup is shown in Fig. 1. Individual neural signals, i.e., action potential spikes, local field potentials, ECoGs, and EEGs, or a combination of these signals, can be used to control a motor prosthesis. Temporal and spectral modulations of these signals are typically mapped (or decoded) to generate a resultant control signal, which is then fed to an actuator. The user is normally provided with a feedback signal on the current state of the device. Visual feedback has been the most common type, although, more recently, augmented feedback systems utilize tactile, proprioception, and other sensory substitution modalities.

BMIs have been shown to have great potential in restoring motor function in patients with severe motor dysfunction, to extend the motor capabilities of amputees, and to assist in neural rehabilitation. Several experimental trials on human subjects and nonhuman primates have shown the viability of BMIs. Nevertheless, their clinical applicability is still limited and is a subject of further research.

Cortical Motor Prosthesis,

Fig. 1 Schematic diagram of a closed-loop BMI. Neural signals acquired through various electrode technologies are processed to extract information such as spike rate, spectral features, etc. The decoder then maps neural information to a control variable of the actuator. The state of the actuator is provided as feedback to the user

Cortical Motor Prosthesis,

Fig. 2 Schematic representation of various recording modalities. EEG electrodes are placed over the scalp. ECoG arrays collect signals from the surface of the cortex, while microelectrode arrays penetrate the brain parenchyma

A typical BMI is comprised of an electrode interface, a signal processing setup, a decoding algorithm, an actuator, and a sensory feedback system. The following sections discuss the various signals acquired using different electrode systems, some of the potential decoders, actuator control strategies, and feedback modalities. The translational nature and the possible pathways of future BMIs are also discussed briefly.

and also by the degree of invasiveness needed to acquire them (see Fig. 2). Table 1 shows the various classes of neural signals acquired from different electrode interfaces. These signals can be decoded to estimate the neural state and/or motor intentions and subsequently used to control a prosthetic device.

Action Potential Spikes

Neural Signals

Recorded neural signals can be classified according to their temporal and spatial resolution

Neurons exhibit brief 1 ms de- and repolarizations, called action potentials or spikes (Fig. 3a), which are carried forward by other synaptically linked neurons. They can be spontaneously

generated or evoked by a stimulus. Volitional intentions or mental imagery of motor actions also elicits neural spikes. These frequency-modulated discrete signal events can be recorded and mapped to an actuator or end effector. Multi-electrode arrays, tetrodes, and microwire arrays are some of the widely used penetrating electrodes used in recording spike activity. Primary motor cortex (M1) has been the *prima facie* location to record neural signals for BMIs, although multiple frontal and parietal cortical areas have also been used by researchers. Over the past 50 years, strong evidence has emerged that M1 neurons encode signals representing limb movement in space. Earlier experiments demonstrated encoding of kinetic variables in M1, while a majority of the present BMIs attempt to decode kinematic variables such as direction, position, and velocity.

Cortical Motor Prosthesis, Table 1 Types of neural signals

Signal type	Temporal resolution (ms)	Spatial resolution (mm)
Action potential spikes	≤ 1	10^{-1}
Local field potentials	~ 10	10^{-1} –1
Electrocorticogram	~ 10	1–10
Electroencephalogram	~ 25	> 10
fMRI	~ 1000	1
fNIRS	~ 1000	> 10

Local Field Potentials

Local field potentials (LFPs) are another class of neurophysiological signaling recorded from penetrating microelectrodes as continuous low-frequency signals (unlike spikes which are discrete events) (see Fig. 3b). The “spatial reach” of these signal sources ranges from < 1 mm (Katzner et al. 2009) to over 1 cm at times depending on the electrode size. Mathematical models and electrophysiological experiments suggest that LFPs represent the aggregate synaptic activity from a group of neurons near the electrode tip. Some experimenters, however, argue that the LFPs are also comprised of “volume-conducted” electrical activity from nonlocal sources. Despite the controversy as to the origin of the LFP, changes in LFP signals have been shown to be linked to motor functions as well as to other important cortical processes such as memory. Its increased spatial resolution compared to noninvasive recording, spectral fidelity, and long-term stability for chronic recording has made this signal modality a viable option for BMI applications. Information from LFPs are extracted from different frequency bands (0–300 Hz) (Andersen et al. 2004; Flint et al. 2012, 2013; Hwang and Andersen 2013). LFPs in certain frequency bands also exhibit widespread synchronous couplings with neurons in motor cortex (Donoghue et al. 1998).

Cortical Motor Prosthesis, Fig. 3 Spike waveforms and local field potential trace

Electrocorticogram

ECoG signals are continuous neural recordings from the surface of the cortex either beneath (subdural) or above (epidural) the dura mater. A strip or grid of electrodes with interelectrode distances of ~ 10 mm (in human implantations) and electrode diameter of ~ 4 mm (with 2.3 mm exposed) is placed on the cortex to record ECoG signals. Computational modeling studies (Slutzky et al. 2010) reported optimal electrode spacing (for maximized information and minimized data redundancy) to be 0.6 mm (subdural) and 0.6–0.9 mm (epidural) for rat cortices and 1.7–1.8 mm (subdural) and 9–13 mm (epidural) for human recordings. ECoGs were originally employed in the domain of clinical studies where human subjects with epileptic seizures or tumors were examined. Recently, ECoGs are shown to have potentials for BMI applications. Higher spatial resolution, bandwidth, signal-to-noise ratio (SNR), immunity to artifacts such as EMG or EOG, and signal stability are some of the advantages of ECoGs over other semi-/noninvasive recording techniques. Similar to LFPs, ECoG activity can be observed at various frequency bands, i.e., theta (4–8 Hz), mu (8–12 Hz), beta (18–25 Hz), and gamma (>40 Hz). The low-frequency bands (mu/beta) are spatially less specific and exhibit amplitude attenuation on movement onset, while the gamma oscillations increase in their amplitude and are spatially specific (Brunner et al. 2009). Schalk et al. (2007) have also observed time-domain features, called the local motor potentials (LMP) that could be used for decoding. Discrete decoding in an online paradigm (Milekovic et al. 2012) has also been reported to establish the viability of ECoG signals for BMI applications.

Electroencephalogram

EEG signals are the least invasive in the hierarchy of neuroelectrophysiological recordings. Differential electrodes placed on the surface of the scalp record the potential difference generated by neuronal sources in and around ~ 10 cm.

Positioning the electrodes is often referred to as the electrode montage and varies between 21, 74, and 142 electrodes located at different scalp landmarks. Events that elicit neural activity would generally be detected as event-related potentials (ERPs) in EEG signals. The averaged ERP component could be *exogenous*, meaning it is recorded within 150 ms of the event, or *endogenous*, a more sustained component. P300 signals are ERPs occurring at an average latency of 300 ms from stimulus event but can vary in latency between 250 and 750 ms and have been a subject of interest in BCI applications (Farwell and Donchin 1988; Li et al. 2010; McFarland et al. 1997, 2010; Nijboer et al. 2008b). EEGs are easily affected by non-brain physiological signals such as EMG, EOG, and ECG, which needs to be detected and eliminated for reliable BMI control.

Metabolic Signals

Apart from the neuroelectrophysiological signals, researchers are also investigating metabolic signals for their suitability in BMI/BCI applications. Sitaram et al. (2009) have used *functional near-infrared spectroscopy* (fNIRS) signals for a BCI discrete classification system. The *fNIRS* technique utilizes *blood-oxygen-level-dependent* (BOLD) responses to detect brain activity. As the neural activity increases, the total hemoglobin and the oxyhemoglobin (oxy-Hb) concentrations in the blood increase, while the deoxyhemoglobin (deoxy-Hb) concentration decreases, in the vicinity of the active brain region. Since oxy-Hb and deoxy-Hb absorb light wavelengths differently, changes in their concentration can be measured using optical diodes serving as light transmitters and receivers. The *fNIRS* has spatial and temporal resolutions in the order of centimeters and seconds, respectively. The most widely studied imaging technique that uses BOLD responses to infer brain activity is *functional magnetic resonance imaging* (fMRI) (Wolpaw and Wolpaw 2012). The oxy-Hb is nonmagnetic, while the deoxy-Hb is slightly magnetic causing a perturbation in the incident magnetic field, thereby changing the strength of the magnetic field. The proportional

changes in the magnetic field due to the presence of deoxy-Hb can then be used in estimating the BOLD response. Since hemodynamic changes are slow, these imaging techniques have temporal resolutions on the order of seconds.

Decoding Systems

Neurons of the motor cortex can encode kinetic variables such as force and torque (Fagg et al. 2009; Cabel et al. 2001; Cheney and Fetz 1980; Sergio et al. 2005; Smith et al. 1975; Taira et al. 1996) or kinematic variables such as position, velocity, and acceleration (Ashe and Georgopoulos 1994; Fu et al. (1993, 1995)). Some neurons encode combinations of these variables (Paninski et al. 2004; Wang et al. 2007; Lawhern et al. 2010). Systems that are used to decipher the encoded values or parameters are termed decoders. However, decoders can map neural data to an output without the need to learn any underlying encoding model. Decoders can be static, adaptive, or stochastic. Linear static decoders, such as the Wiener filters, are widely used due to their simplicity.

Static Decoders

One of the earliest decoding algorithm in systems neuroscience is the so-called “population vector” algorithm that has been used to relate ensemble neural firings to movement parameters, typically direction and velocity. Georgopoulos et al. (1986) observed that neurons tend to fire the most when the actual movement vector is aligned with a direction termed the “preferred direction” and follow a cosine tuning curve in their rate of discharge. The firing rate ($z(D)$) is related to the movement direction as given in Eq. 1:

$$z(D) = \alpha + \gamma \cos \theta_{PD} \quad (1)$$

where θ_{PD} is the angle between the preferred direction P of the neuron and the actual movement direction D . The movement direction can then be decoded by the weighted sum of the neural

firing rate from an ensemble of N neurons, as given by Eq. 2:

$$V(D) = \sum_{i=1}^N f_i(D) \quad (2)$$

where $f_i(D) = (z_i(D) - \alpha_i)P_i$.

Note that each neuron's firing history over multiple time points is not explicitly included in the population decoding.

Wiener filters take into account these time-delayed neural activities and map them to a control variable, either kinetic or kinematic (see Eq. 3):

$$\hat{y} = Z\beta \quad (3)$$

where the neural activity matrix Z (columns corresponding to different time delays of multiple neurons and rows corresponding to different time points) is mapped to the control variable $\hat{y}$ via the system coefficients β (a column vector where each component corresponds to a different time delay). Note that the Wiener filter does not begin with an explicit encoding model like the population vector algorithm. The Wiener filter has the advantage that a closed-form solution for the beta coefficients exists that is optimal by minimizing the error between the predicted and training control variable. With limited training data, regularization terms can be added to the error equation such that large coefficients are penalized resulting in the ridge-regression solution for β . Solving for β in a ridge-regression framework is shown in Eq. 4, with a ridge parameter λ :

$$\beta = (Z^T Z + \lambda I)^{-1} Z^T y \quad (4)$$

Adaptive Decoders

Decoders capable of adapting to the changing input signal statistics are referred to as adaptive decoders. The neural activity matrix is often noisy and the intended motor output can be estimated using optimal linear filters such as the Kalman filter (which adapts the filter gain according to

Cortical Motor Prosthesis, Table 2 Kalman filter algorithm

$x_k = Ax_{k-1}$	State prediction
$\Sigma_k = A\Sigma_{k-1}A^T + R$	Covariance prediction
$K_k = \Sigma_k C^T (C\Sigma_k C^T + Q_k)^{-1}$	Kalman gain
$x_k = \tilde{x}_k + K_k(z_k - C\tilde{x}_k)$	State update
$\Sigma_k = (I - K_k C)\Sigma_k$	Covariance update

the changing covariance estimate of the neural signal). BMIs use a discretized, time-invariant (constant parameters) version of the filter. Kalman filters are linear Gaussian-structured filters and can be easily understood in a state-space framework. It is intended to estimate the state vector, x_k , at each time step taking into account the observed firing rate z_k . In BMIs, the state vector could be the kinematics of a prosthetic limb, $x_k = [\text{position}, \text{velocity}, \text{acceleration}]^T$. The state transition equation for x_k is a linear function given by Eq. 5:

$$x_k = Ax_{k-1} + \epsilon_k \quad (5)$$

where A is the state transition matrix and $\epsilon_k \sim \mathcal{N}(0, R)$ models the transition uncertainty. Similarly, the neural firing rates are again linearly related to the state vector:

$$z_k = Cx_k + \delta_k \quad (6)$$

The firing rate noise is described by $\delta_k \sim \mathcal{N}(0, Q)$. The algorithm for Kalman filtering can be described as a two-step process where the state transition and its covariance are predicted in the first step and subsequently updated using the observed neural firing rates. Table 2 shows the pseudo-code version of the Kalman filter. The matrices A , R , C , Q are chosen such that the joint probability between the kinematic variable X_N and the firing rates Z_N from N training sets, $p(X_N, Z_N)$, is maximized (Black and Donoghue 2007). The closed-form solution yields the matrices as described in Table 3 (Wu et al. 2006). As the state transition progresses with time, it becomes nearly independent of the initial state, and hence, a reasonably chosen random initial condition should suffice for a satisfactory filtering.

Cortical Motor Prosthesis, Table 3 Kalman filter matrices

$A = \left(\sum_{k=2}^N x_k x_{k-1}^T \right) \left(\sum_{k=2}^N x_{k-1} x_{k-1}^T \right)^{-1}$
$R = \frac{1}{N-1} \left(\sum_{k=2}^N x_k x_k^T - A \sum_{k=2}^N x_{k-1} x_{k-1}^T \right)$
$C = \left(\sum_{k=1}^N z_k x_k^T \right) \left(\sum_{k=1}^N x_k x_k^T \right)^{-1}$
$Q = \frac{1}{M} \left(\sum_{k=1}^N z_k z_k^T - C \sum_{k=1}^N x_k x_k^T C^T \right)$

Recently, a modified version of the Kalman filter, referred to as recalibrated feedback intention-trained Kalman filter (ReFIT-KF), was reported that allows users to maintain zero velocity when the target is reached (Gilja et al. 2012). According to this algorithm, in a 2D cursor reaching experiment that decodes both position and velocity, the uncertainty in the estimate of the position p_k was “causally intervened” with a more certain position $\hat{p}_k$ such that the intended movement is always directed towards the minimal path to the target.

Nonparametric Decoders

Under the Bayesian framework, the decoding paradigm can be viewed as estimating the maximum a posteriori value of $p(x_t|Z_t)$, i.e., the movement variable conditioned on the firing rate (Wu et al. 2006). The posterior probability is related to the prior and the likelihood (under Markov assumptions) as

$$p(x_t|z_t) \propto p(z_t|x_t) \times \int p(x_t|x_{t-1})p(x_{t-1}|Z_{t-1})dx_{t-1} \quad (7)$$

Here, the prior and the likelihood can be arbitrary distributions, although Kalman filter assumes them to be Gaussian. In order to decode posterior distributions that are nonlinear and non-Gaussian, nonparametric methods such as particle filters can be used. Particle filters represent the posterior distribution using a set of random samples, or *particles*, (N_p), and their associated state estimate and weights, $\{x_{i,t}, \mathcal{W}_{i,t}\}$, where $i = 1, \dots$,

N_p . There are several flavors of particle filtering available, and one interesting variant, the auxiliary particle filter (APF) (Chen 2003), is discussed here.

The objective is to determine an approximation of the posterior distribution:

$$\hat{p}(x_t|Z_t) \approx \sum_{i=1}^{N_p} \mathcal{W}_{it} \delta(x_t - x_{it}) \quad (8)$$

In order to estimate the weights $\mathcal{W}$, the APF approach uses a two-step process which samples weights from a proposal distribution (q_a) and updates the weight according to some likelihood estimate. Since the actual posterior distribution is unknown and cannot be sampled from, the proposal distribution is used. This could be a simple distribution with Gaussian parameters or a kernel that reflects neural tuning curves from the ensemble. An algorithmic representation of the APF is given in Table 4. These steps are repeated for every time step. Particle filters have been used in decoding the hippocampal place cells (Brown et al. 2001; Mountney et al. 2009) and retinal neurons (Brown et al. 2003), and a real-time implementation is discussed in Mountney et al. (2011).

Cortical Motor Prosthesis, Table 4 Particle filter algorithm

$\hat{x}_{i,t} \sim q_a(x_t x_{i,t-1}, z_t)$	Sample from proposal distribution
$W_{i,0} = 1/N_p, i = 1, \dots, N_p$	Initialize the weights
$\hat{\mathcal{W}}_{i,t} = \mathcal{W}_{i,t-1} \times \frac{p(z_t \hat{x}_{i,t})p(\hat{x}_{i,t} \hat{x}_{i,t-1})}{q_a(x_{i,t} \hat{x}_{i,t-1}, z_t)}$	Calculate the 1st stage weights
$\bar{W}_{i,t} = \frac{\hat{\mathcal{W}}_{i,t}}{\sum_{n=1}^{N_p} \hat{\mathcal{W}}_{n,t}}$	Normalize weights
$\hat{x}_t \sim q_b(\hat{x}_t \hat{x}_{t-1}, z_t)$	Resample from the new proposal distribution
$\mathcal{W}_{i,t} = \mathcal{W}_{i,t-1} \times \frac{p(z_t \hat{x}_{i,t})p(\hat{x}_{i,t} \hat{x}_{i,t-1})}{q_b(\hat{x}_{i,t} \hat{x}_{i,t-1}, z_t)}$	Calculate the 2nd stage weights
$\mathcal{W}_{i,t}^{aux} = \frac{\mathcal{W}_{i,t}}{\sum_{n=1}^{N_p} \mathcal{W}_{n,t}}$	Normalize weights
$p(x_t Z_t) \approx \sum_{i=1}^{N_p} \mathcal{W}_{i,t}^{aux} \delta(x_t - \hat{x}_{i,t})$	Posterior distribution

Decoder Initialization

The process of mapping *a priori* neural signals to any control variables, thereby determining the decoder filter coefficients, is termed decoder initialization. The decoder coefficient matrix to transform neural firing rates into control signals can be estimated by concurrently recording the neural data and the actual kinematic/kinetic variable, as the subject executes the task. This popular mapping approach is often referred to as *biomimetic decoding*. When the subjects have intact nervous systems and limbs, performing the kinematic task is trivial and the biomimetic decoding is preferred. However, the mapping becomes nontrivial when the kinematic variables are not observable, such as in paralyzed or amputee patients. This could be resolved by resorting to either (i) an observation-based initialization or (ii) an unsupervised decoder that does not need the kinematic variable. Subsequent sections below explain briefly the different decoder initialization approaches. Once the decoder is initialized, it could remain static or adaptive.

Observation-Based Initialization

Several regions of the cortex have neurons exhibiting congruent activity during active movement as well as passive observation of the same task (Dushanova and Donoghue 2010; Tkach et al. 2008). Primary motor cortical activity profiles were first reported to be similar when recorded from macaques engaged in a particular task and also while merely observing the same task (Tkach et al. 2008). This idea could be used to initialize a decoder where the subject can imagine a particular movement or observe a relevant task and the neural signals are recorded and mapped to the observed movement. In a BMI experiment reported in Balasubramanian et al. (2013), neural activity collected from the primary motor cortex, as a chronically amputated macaque was observing a robot moving in a desired trajectory, was used to initialize a decoder. Clanton et al. (2013) have used

observation-based decoder initialization in controlling a multiple DOF robot involving translation, rotation, and grasp aperture.

Unsupervised Decoder Initialization

The unsupervised initialization approach ignores the unobservable kinematic variable and shifts the emphasis on the neural signal dynamics to determine the decoder filter coefficients. In one unsupervised approach, decoders are assumed to function as linear correlators and the coefficients are sampled from a multivariate distribution with covariances matching the neural data. Such a decoder is expected to have a matching frequency response to the neural dynamics. A minimum-norm Mahalanobis distance solution was implemented in Badreldin et al. (2013) for initializing a velocity decoder. The coefficients were chosen such that the Gaussian properties of the output are preserved.

At a system level, the decoders and the ensemble of neurons driving them can be viewed as two coupled systems, and either or both can be adaptive. Adaptive decoders (discussed in the previous section) can minimize control errors by adapting the filter coefficients. On the other hand, when a static decoder is initialized using the unsupervised approach, adaptation occurs at the neuronal side of the coupled system.

Operant Conditioning

A proven technique in learning to adapt to a decoder is *operant conditioning*, which relies on providing a reinforcement stimulus whenever a desired behavior occurs (Seel 2012). As learning occurs, the occurrence frequency of the desired behavior increases. In BMI experiments with nonhuman primates, desired behavior can be reinforced using juice reward or fruit bits. Positive reinforcements have been used by Fetz and colleagues in training monkeys to volitionally modulate single-neuron firing activity (Fetz 1969; Fetz and Finocchio 1971). Fetz and Finocchio (1975) also showed that volitional neural modulations can be achieved with complete dissociation from any peripheral muscle

contractions. This degree of flexibility of motor cortex (Wander et al. 2013) has been harnessed in developing BMIs further. Several experiments have successfully used operant conditioning as a mode in BMI training. Recent experiments with a primate model of amputation have used operant conditioning in training macaques to control a multiple DOF robot (Balasubramanian et al. 2013).

Actuator Modalities and Controlled Devices

Experimental BMI studies have reported extensively on cortical control of virtual objects such as computer cursors in 2D or 3D space (Black et al. 2003; Hatsopoulos et al. 2004; Santhanam et al. 2006; Serruya et al. 2002; Shpigelman et al. 2008; Taylor et al. 2002). Tasks include reaching predefined target locations either in sequence or at random, tracking a randomly moving target, free-choice targets with varied reward probability, etc. These experiments were useful in devising a translational pathway to neural motor prosthesis and rehabilitation. Robots, whole-arm manipulators, and virtual avatars allow BMIs to operate many degrees of freedom in a 3D space (Carmena et al. 2003; Lebedev et al. 2005). When controlling a multiple DOF robot using BMIs, decoded signals can (a) operate directly on the joint space controlling the individual joints or (b) define the end-effector position and orientation, while the controllers determine the instantaneous joint configuration. Smooth movement controls can be achieved with a minimum-jerk (Flash and Hogan 1985; Shadmehr 2005) solution, mimicking regularities in biological motion. For nonredundant robots (number of DOFs ≤ 6), a unique inverse kinematic solution is achievable for a given end-effector definition. Redundant robots can have infinite solutions to a given spatial coordination and orientation and hence need numerical controllers or constrained controllers such as null-space controllers (Nemec and Zlajpah 2000; Corke 2011). Finer motor controls such as grasping can be controlled in a reduced dimension

synergistic space rather than the joint space. A large proportion of the variance observed in natural grasp kinematics can be accounted for with few principal components (Ingram et al. 2008; Mason et al. 2001; Santello 2002). For example, the hand has more than 20 DOFs (say, n) and any hand posture belongs to an R^n dimension representation. However, natural grasping behavior resides in a much smaller representational space so that dimensionality reduction techniques such as principal component analysis can be used. The principal components (or *eigengrasps* (Ciocarlie et al. 2007)) of this high-dimension space form a synergistic basis for the complex postures of the hand. A single basis can then be used to represent grasp aperture and is independent of the number of fingers. Similarly, other bases can represent pronation/supination, thumb abduction/adduction, etc. These basis sets offer a direct mapping between a decoded control signal and a control synergy.

Feedback in a BMI

In BMIs, feedback about the state of the prosthesis is essential to compensate for any movement errors. Visual feedback is the predominant feedback modality that uses the natural sensory pathway. Additionally, proprioceptive, tactile (Nicoletis 2003), and, to some extent, auditory feedback (Nijboer et al. 2008a; Schreuder et al. 2010) are being investigated as promising modalities for BMIs. Artificial feedback systems provide tactile and/or proprioceptive feedback in the form of mechanical stimulation of peripheral nerves or electrical stimulation of residual nerves (Hatsopoulos and Donoghue 2009). Extended physiological proprioception (EPP), an approach which uses residual tactile and proprioceptive sensations as feedback pathways, is another important natural form of feedback to augment the visual system. Subjects with spinal cord injury (SCI) and with subsequent motor dysfunction may retain some residual somatosensation (Eide et al. 1996; Finnerup et al. 2004; Grill et al. 2009), which could be taken advantage of for providing EPP feedback.

Multisensory Feedback

Current BMIs are exploring different ways to effectively integrate information from multiple sensory modalities. It is well established that sensory inputs alter motor decisions, when provided as feedback. Experimental evidence has suggested that augmenting feedback with more than one sensory modality provides usable mutual information to the motor cortex (Suminski et al. 2009). Alterations in movement trajectories were observed as early as 70 ms following a proprioceptive cue (Crago et al. 1976). Visual feedback is relatively slow and influences the motor commands around ~150 ms. Macaques performing a target tracking task in a 2D space were able to reach the target faster when the visual feedback was augmented with proprioception. An exoskeleton was used by Suminski et al. (2010) to provide kinesthetic feedback, in addition to vision, about cursor positions in the 2D plane. The exoskeleton is one way of providing EPP to BMI users. Under congruent feedback conditions, BMI performance improved by 40% in terms of the time to target and path length (the ratio between the actual path and the minimal path to target).

Sensory Substitution

In neuromotor prosthesis control, providing biologically plausible sensory feedback (primarily haptic feedback) to the user is a challenging issue and substituted feedback is viable in certain situations. Haptic feedback can be substituted by alternative feedback modalities such as vibrotactile or pneumatic pressure and delivered to a different region of the body (Kaczmarek et al. 1991). Vibrotactile feedback to the tongue has been a successful substitution approach used by visually impaired persons in detecting obstacles (Chebat et al. 2011). Several studies have used vibrotactile stimulation as substituted feedback delivered to the biceps of an intact arm, or residual arm in cases of amputees, to indicate a 1D kinetic variable, such as the output of a pressure sensor (Aniruddha et al. 2007). The Pacinian mechanoreceptors (Mountcastle et al. 1972) are, in general, the target

receptors and determine the applied vibration frequency (~200 Hz). Parameters such as the frequency, intensity, timbre, duration, and body location can be modulated at the receptor level to deliver various forms of feedback information (Cincotti et al. 2007).

Another direct substitution for force feedback is the use of a pneumatic cuff delivering radial pressure to the biceps in proportion to the grasp pressure exerted by the prosthesis (Patterson and Katz 1992). In the BCI context, users with substituted feedback were able to generate relatively more accurate control signals.

Bidirectional Brain-Machine Interfaces

Rich somatosensory feedback can be provided directly to the brain via electrical stimulation of the somatosensory cortex. Intracortical microstimulation (ICMS) is a technique used to deliver small amounts of currents (~25–60 μ A) to neurons via electrodes or microwires (O'Doherty et al. 2011). The delivery rate of stimuli to the neurons is a parameter controlled in delivering discriminable tactile feedback. O'Doherty et al. (2009) has reported using a stimulation frequency of 30 and 60 Hz with pulse widths of 150–200 μ s. Berg et al. (2013) have used ICMS to deliver graded percepts of force stimuli exerted on a prosthetic finger. Amplitude of four graded signals representing the different mechanical stimuli was modulated in proportion to time-varied force output of the prosthetic finger, and equivalent currents were delivered. ICMS to S1 can be used for directional instruction, active tactile sense, or even to represent somatotopic mapping of a body in 3D space (Lebedev and Nicolelis 2011).

BMI Applications in Human Patients

Although currently there do not exist commercially available brain-machine interfaces for human patient use, there have been attempts in research and preclinical settings to examine the capabilities of such systems in tetraplegic patients. Phil Kennedy and colleagues were the first to demonstrate

that severely disabled “locked-in” patients (due to brainstem stroke and ALS) could control switches and cursor movements using spikes and local field potentials from implanted microwires encased in a glass cone (Kennedy and Bakay 1998; Kennedy et al. 2000, 2004). Building on this early work, an FDA clinical trial was initiated on four patients with tetraplegia due to spinal cord injury, ALS, and brainstem stroke using the BrainGate system. This system consisted of a silicon-based 100-microelectrode array implanted in the primary motor cortex. It was shown in two of these patients that effective two-dimensional cursor control was possible using spikes from approximately 27 neurons (Hochberg et al. 2006). More recently, the second-generation BrainGate system (BrainGate 2) has demonstrated that chronic tetraplegics could control three-dimensional reaching and one-dimensional grasping of a multi-articulate robot using motor cortical spiking activity from the implanted silicon-based electrode array (Hochberg et al. 2012). In addition, another group has shown that an individual with tetraplegia could control up to seven independent degrees of freedom of a prosthetic limb including three-dimensional translation, three-dimensional orientation, and grasp using the same implanted array technology (Collinger et al. 2013). A somewhat less invasive approach using field potential oscillations up to 200 Hz recorded from the surface of the cortex via ECoG electrodes has demonstrated effective three-dimensional cursor control in a human tetraplegic (Wang et al. 2013). In contrast to these invasive methods, EEG has been extensively used in human subjects relying primarily on voluntary modulation of slower frequency oscillations below 40 Hz over somatosensory and motor cortices. Despite the weaker information content in EEG-based recordings, it has been possible to control up to three dimensions of cursor movement using voluntary modulation of slow sensorimotor rhythms (McFarland et al. 2010).

Corticothalamic Feedback: Large-Scale Synchrony

Alain Destexhe

Unit of Neuroscience Information and Complexity (UNIC), Paris-Saclay University, Institute of Neuroscience (NeuroPSI), Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

The thalamus is a pacemaker for several types of brain oscillations, such as sleep spindles. Although these oscillations are generated within thalamic circuits, their triggering and large-scale synchrony depends on cerebral cortex. In particular, it depends on the descending excitatory action of the cortex on the thalamus. Computational models show that the inhibitory-dominant character of this “corticothalamic feedback” can explain the large-scale synchrony of oscillations in cerebral cortex.

Detailed Description

Introduction

The fact that the brain produces oscillations was discovered as soon as electroencephalogram (EEG) recordings of brain activity were available. The first human EEG recordings reported oscillations, which type, frequency, and amplitude highly depend on behavioral state (reviewed in Steriade 2003). In an alert, awake subject, the EEG is dominated by low-amplitude fast activity (“desynchronized EEG”) with high-frequency oscillations (beta, gamma), whereas during slow-wave sleep, the EEG shifts to large-amplitude, slow oscillations. The early stage of slow-wave sleep is associated with EEG spindle waves, which occur at a frequency of 7–14 Hz. As sleep deepens, waves with slower frequencies (0.3–4 Hz), including delta waves and slow oscillations, appear and progressively dominate the EEG. During paradoxical sleep, also called rapid eye movement (REM) sleep, EEG activities resemble those of wakefulness.

The cellular mechanisms of slow-wave sleep oscillations have been investigated since the first extracellular and intracellular recordings in mammals. The major brain regions which have been identified are the thalamus and cerebral cortex, which are densely linked by means of reciprocal projections. The activities of thalamic and cortical neurons during sleep have been largely documented by electrophysiological studies. The cellular mechanisms underlying these oscillations depend on many factors, such as the connectivity and intrinsic properties of the different types of thalamic and cortical neurons. To determine these cellular mechanisms, it is necessary to use computational models, which are based on experimental data, and suggest mechanisms and, if possible, predictions to test them. This type of interaction has been quite successful in the (still ongoing) exploration of the mechanisms of sleep oscillations.

The cellular mechanisms leading to the genesis of spindle oscillations by thalamic circuits were reviewed in another entry (► “[Spindle Oscillations: Models](#)”). Spindle oscillations are generated by interacting thalamic neurons, as illustrated in Fig. 1. Thalamocortical (TC) and

thalamic reticular (RE) cells, endowed with their intrinsic bursting properties and connected via glutamate (AMPA) and GABA_A receptors, can generate spindle oscillations reproducing the typical features observed in intracellular recordings (reviewed in Destexhe and Sejnowski 2001, 2003).

Propagation or Large-Scale Synchrony?

The initiation of spindle oscillations and their distribution in large-scale circuits were investigated using multiple recordings in vivo (Contreras et al. 1996) and in vitro (Kim et al. 1995). Spindle oscillations in vitro showed traveling wave patterns, with the oscillation typically starting on one side of the slice and propagating to the other side, at a constant propagation velocity (Kim et al. 1995). Traveling spindle waves were simulated by computational models of networks of interconnected TC and RE cells (one-dimensional extensions of the circuit shown in Fig. 1), in two independent modeling studies (Destexhe et al. 1996; Golomb et al. 1996). These models were similar in spirit to the circuit shown in Fig. 1a but assumed that there was a topographic connectivity between TC and RE layers, consistent with anatomical data. Under these conditions, the models generated traveling waves consistent with in vitro data.

However, in contrast to thalamic slices, the intact thalamocortical system in vivo showed that spindle oscillations are remarkably synchronized over extended thalamic and cortical regions, with little evidence for propagation (Fig. 2, left). This large-scale synchrony was lost when the cortex was removed (Fig. 2, right). In this case, propagating oscillations were seen, suggesting that although the oscillation is generated by the thalamus, its large-scale synchrony depends on the cortex (Contreras et al. 1996).

Thalamocortical Networks

To investigate possible mechanisms underlying large-scale synchrony, a thalamocortical network model was developed by combining a previous model of thalamic slices with a model of deep cortical layers (see details in Destexhe et al. 1998). The principal prediction of this model was that, in order to generate large-scale coherent oscillations, one has to take into account the powerful action of cortex on thalamus (via corticothalamic fibers) and, most importantly, the cortex had to recruit the thalamus primarily through the RE nucleus. Because of the powerful inhibitory action of RE cells, the action of corticothalamic input is “inhibitory dominant” on TC cells, which property is essential to maintain large-scale synchrony by synchronizing the

Corticothalamic Feedback: Large-Scale Synchrony, Fig. 1 Computational model of spindle waves generated by TC-RE interactions. (a) Scheme of a simple circuit consisting of two TC and two RE cells, interconnected

with glutamatergic (AMPA) and GABAergic receptors (GABA_A and GABA_B). (b) Activity of two model neurons during simulated spindle waves. (Modified from Destexhe et al. 1996)

In vivo experiments

Corticothalamic Feedback: Large-Scale Synchrony, Fig. 2 The large-scale synchrony of spindle oscillations. Multiple extracellular field potential recordings (Th1–Th8) in the thalamus of cats *in vivo* are shown in two cases. *Left*: in the intact thalamocortical system (intact), the

oscillations were synchronized over large distances (7 mm between Th1 and Th8). *Right*: after removal of the cortex (decorticated), the large-scale synchrony was largely abolished. (Modified from Contreras et al. 1996)

rebound bursts of TC cells (Destexhe et al. 1998). This property of inhibitory dominance is generally observed intracellularly in thalamic neurons when stimulating the cortex. In these conditions, the same model was capable of generating large-scale synchrony in the presence of the cortex and traveling wave activity in the isolated thalamus (Fig. 3). Consistent with these models, propagating activity has indeed been observed in the thalamus of decorticated cats *in vivo* (Contreras et al. 1996).

The “inhibitory-dominant” character of corticothalamic feedback on thalamic relay cells has multiple important consequences. Not only it can explain the large-scale synchrony of spindle oscillation, but it can also explain the genesis of some pathological situations such as absence epileptic seizures (Destexhe et al. 1998), as detailed in another entry (► “Slow Oscillations and Epilepsy: Network Models”). As a result of inhibitory dominance, a too strong corticothalamic feedback can over-activate thalamic GABA_B receptors and entrain the *physiologically intact* thalamus into hypersynchronous rhythms at ~3 Hz. This scheme

may explain the genesis of absence seizures, which are hypersynchronous ~3 Hz rhythms that appear suddenly in the thalamocortical system. These seizures can be provoked experimentally by increasing cortical excitability while keeping a physiologically intact thalamus (reviewed in Gloor and Fariello 1988). The thalamocortical model accounts for those experiments and can simulate seizures based on inhibitory-dominant corticothalamic feedback (Destexhe et al. 1998). This model directly predicted that manipulating corticothalamic feedback should entrain intact thalamic circuits to generate hypersynchronous rhythms at ~3 Hz, a prediction which has been verified by two independent studies (Blumenfeld and McCormick 2000; Bal et al. 2000). A similar mechanism, with a different balance between GABA_A and GABA_B receptors, can also generate faster hypersynchronous rhythms (around 5–10 Hz), as observed in rat or mouse experimental models of absence seizures.

In conclusion, in this entry, we have reviewed evidence that the mutual interactions between cortex and thalamus are a very powerful

Corticothalamic Feedback: Large-Scale Synchrony, Fig. 3 Modeling the large-scale synchrony of spindle oscillations. Computational models of thalamocortical networks displaying large-scale synchrony when cortex was

present (*left*) and local synchrony with traveling wave activity in the isolated thalamus (*right*). (Modified from Destexhe et al. 1998)

mechanism to synchronize oscillations over multiple brain areas. This mechanism was revealed by performing recordings in thalamus and cortex, interconnected or isolated from each other, as well as by using computational models. The models revealed that a critical ingredient is that the cortex recruits the thalamus essentially through inhibition. This mechanism can explain all experimental measurements, and it can also explain the genesis of a form of hyper-synchronized pathological oscillations by the thalamocortical system.

Coupled Oscillations in Neural Control of Breathing

Yaroslav Molkov

Department of Mathematical Sciences, Indiana University – Purdue University Indianapolis, Indianapolis, IN, USA

Dual-generator concept

Definition

The respiratory rhythm in mammals is generated by a respiratory central pattern generator (CPG) in

the brainstem and encompasses both pons and medulla (see Fig. 1; Alheid and McCrimmon 2008; Smith et al. 2013). The pre-Bötzinger complex (pre-BötC), located in the ventrolateral region of the medulla, is the putative kernel of rhythmic inspiratory activity. The pre-BötC interacts with the expiratory neurons of Bötzinger complex (BötC) to generate primary respiratory oscillations. These oscillations are defined by both the intrinsic biophysical properties of neurons involved and the network interactions within and between the pre-BötC and BötC. Through the premotor neurons of the rostral ventral respiratory group (rVRG), these oscillations produce rhythmic drive to phrenic motoneurons that through the phrenic nerve (PN) control movements of the diaphragm and lung inflation.

A distinct site of neural oscillations involved with the respiratory function, located more rostral to the pre-BötC, was identified in vitro, in the isolated brainstem-spinal cord preparation. The source of these oscillations, which was termed parafacial respiratory group (pFRG), was found to reside within the retrotrapezoid nucleus (RTN)

Coupled Oscillations in Neural Control of Breathing, Fig. 1 Parasagittal view of brainstem at the level of nucleus ambiguus. **Abbreviations:** 5n trigeminal nerve, 7 facial nucleus, 7n facial nerve, AmbC compact part of nucleus ambiguus, BötC bötzinger complex, cVRG caudal division of ventral respiratory group, KF kölliker-fuse nucleus, Mo5 motor nucleus of the trigeminal nerve, PB parabrachial nucleus, pFRG parafacial respiratory group, Pn basilar pontine nuclei, pre-BötC pre-bötzinger complex, RTN retrotrapezoid nucleus, rVRG rostral division of ventral respiratory group, scp superior cerebellar peduncle, SO superior olive, sol solitary tract, sp5 spinal trigeminal tract, VRG ventral respiratory column of the medulla, VRG ventral respiratory group (Adapted from Alheid and McCrimmon (2008) with permission)

or partially overlaps with it (Onimaru and Homma 2003; Janczewski and Feldman 2006). The pFRG oscillations emerge with increased metabolic demands (e.g., hypercapnia) and via abdominal nerve (AbN) drive abdominal muscles enabling forced lung deflation (active expiration). This rhythmic activity is coupled to the pre-BötC oscillations so that generated bursts represent late-expiratory (late-E) or sometimes biphasic (containing pre-inspiratory, pre-I, and post-inspiratory, post-I, components) discharges (Janczewski and Feldman 2006; Abdala et al. 2009).

Several competing concepts concerning the appearance of RTN/pFRG oscillations and their physiological function have been suggested (Janczewski et al. 2002; Onimaru and Homma 2003; Abdala et al. 2009; Molkov et al. 2010). However, there are still heated debates on the exact physiological role of RTN/pFRG oscillations, the specific conditions for their emergence, and the nature and mechanisms of the interactions between the BötC/pre-BötC and RTN/pFRG oscillators.

Detailed Description

From mathematical viewpoint, the most striking experimental observations that evidence the existence of two distinct oscillators in neural control of breathing are the so-called *quantal slowing* of phrenic rhythm (Janczewski and Feldman 2006; Mellen et al. 2003) and *quantal acceleration* of abdominal discharges (Abdala et al. 2009; Molkov et al. 2010).

The *quantal slowing* of the pre-BötC and/or PN oscillations has been demonstrated with administration of opioid agonists in the in vitro isolated brainstem-spinal cord preparation and in vivo (Mellen et al. 2003; Janczewski and Feldman 2006). This phenomenon consists of a stepwise reduction in the frequency of pre-BötC (and/or PN) oscillations resulting from deletion (missing) of a single or a series of inspiratory bursts in the output activity recorded. Although the exact pharmacological effect of opioids is unknown, the general assumption has been that opioids reduce the excitability of pre-BötC

neurons either directly or indirectly (via the suppression of excitatory synaptic transmission within the pre-BötC).

Similarly, *quantal acceleration* of late-E abdominal activity was observed with development of hypercapnia (elevation of CO₂) in the in situ arterially perfused rat brainstem-spinal cord preparation (Fig. 2, see Abdala et al. 2009; Molkov et al. 2010) and in vivo (Iizuka and Fregosi 2007). Experimental studies in the perfused in situ preparation have shown that under baseline normocapnic metabolic conditions (5% CO₂), the abdominal nerve motor output (AbN) typically exhibits a low-amplitude expiratory (post-I) activity. Switching to hypercapnic (7–10% CO₂) conditions evoked large amplitude late-E (also called pre-I) bursts in the AbN. These late-E discharges emerge in AbN at 7% CO₂ followed by a progressive increase in their frequency as the CO₂ concentration in the perfusate is incremented to 10%. Importantly, although the frequency of late-E bursts increases with CO₂, these bursts remained coupled (phase-locked) to the inspiratory bursts in the PN (Fig. 2). With the development of hypercapnia, the ratio of late-E burst frequency to the PN burst frequency showed a stepwise (quantal) increase from 1:5 and 1:4 (not shown) to 1:3, 1:2, and, finally, 1:1 (at 10% CO₂). On returning CO₂ to the control levels, the ratio showed a stepwise reversal.

Several computational models of interacting neural oscillators related to generation of respiratory activity with various levels of complexity have been proposed. The most detailed description of possible interactions between the BötC/pre-BötC and RTN/pFRG circuits (Fig. 3; Molkov et al. 2010) was developed as an extension of the respiratory CPG model proposed earlier by Smith et al. (2007) (see ► “Computational Models of Mammalian Respiratory CPG”). According to that description, the BötC/pre-BötC oscillator controls the emergence of late-E oscillations in RTN/pFRG and their frequency and phase by inhibiting RTN/pFRG oscillator during both expiration (via post-I inhibition) and inspiration (via early-I inhibition). This inhibition prevents late-E activity in RTN/pFRG and AbN to occur under normal metabolic conditions.

Coupled Oscillations in Neural Control of Breathing, Fig. 2 Quantal acceleration of late-E discharges in the in situ brainstem-spinal cord preparation. The phrenic nerve (PN, red) and abdominal nerve (AbN, black) activities are shown by pairs of traces: raw recording (lower trace) and integrated activity (upper trace). PN bursts define

inspiratory phases of respiratory cycles (some highlighted by vertical pink bars), and interburst intervals correspond to expiratory phases. Late-E discharges in AbN occur at the end of expiration, just prior to inspiration (highlighted by gray bars) (Adapted from Molkov et al. (2010) with permission)

Coupled Oscillations in Neural Control of Breathing, Fig. 3 The schematic of the model. Each population (shown as a *sphere*) consists of 50 single-compartment neurons described in the Hodgkin-Huxley style. The populations are denoted according to their firing pattern: *post-I* post-inspiratory, *aug-E* augmenting expiratory, *pre-I/I* pre-inspiratory/inspiratory, *early-I* early inspiratory, *ramp-I* ramping inspiratory, *late-E* late expiratory. BötC/pre-BötC oscillator (Smith et al. 2007) controls RTN/pFRG oscillator (the intrinsically rhythmic late-E population) by inhibitory inputs from post-I and early-I

(1) neurons. Excitatory late-E neurons send their axons to bulbospinal premotor expiratory (E) neurons in cVRG, representing the source of AbN activity. The model includes three sources of tonic excitatory drive: pons, RTN, and raphé (shown as green triangles) which project to multiple neural populations in the model. The late-E population receives an additional external drive simulating the effect of hypercapnia. All model equations and parameters can be found in Molkov et al. (2010) (Adapted from Molkov et al. (2010) with permission)

The excitability of the late-E population in RTN/pFRG in the model is highly sensitive to hypercapnia which causes their depolarization (see Fig. 3). At some level of CO_2 , this excitation

overcomes the inhibition of late-E population in RTN/pFRG by BötC/pre-BötC circuits and initiates late-E rhythmic activity which translates to AbN. The late-E bursts initially emerge at a very

Coupled Oscillations in Neural Control of Breathing, Fig. 4 Quantal acceleration of AbN activity in the model. The late-E bursts in the AbN are always phase-locked with PN bursts, and the ratio between AbN and PN frequencies quantally increased through 1:3 (at drive to late-E = 0.32) to 1:2 (0.34) and to 1:1 (0.36) as “hypercapnic” drive to the late-E population of RTN/pFRG gradually increases

mimicking progressive hypercapnia. The *lower panel* shows the dependence of oscillation periods in AbN (black circles) and PN (red squares) on the hypercapnic drive (*horizontal axis*). The period of AbN late-E discharges sequentially jumps from 4 PN periods to 3, then to 2, and finally to 1 (Adapted from Molkov et al. (2010) with permission)

low frequency, but as CO_2 level progresses (Fig. 4), the frequency of late-E discharges quantally increases, until it reaches 1:1 ratio with the BötC/pre-BötC oscillations that define PN output. In contrast, strong hypoxia or anoxia can evoke the RTN/pFRG oscillations through a reduction of inhibition, specifically the post-I inhibition, and produce an effect similar to hypercapnia by shifting the balance between inhibition and excitation at the level of RTN/pFRG late-E neurons.

Rubin et al. (2011) performed thorough qualitative analysis of the reduced model and explained the regimes of *quantal acceleration* and *quantal slowing* in terms of synchronization of the BötC/pre-BötC and RTN/pFRG oscillators. The dynamics of each oscillator can be represented by a stable limit cycle in some phase space. The phase space of a system of two coupled oscillators is a Cartesian product of the phase spaces of each oscillator. The corresponding limit set is a 2D

invariant torus, and the behavior of this system is represented by a trajectory on this torus. If the ratio of oscillation frequencies of the two oscillators is rational (i.e., equal to N/M , for some integers N and M), then this trajectory is closed, indicating $N:M$ synchronization between oscillators, where N and M represent numbers of rotations around two orthogonal circles that together span the torus.

With changing conditions, the system of coupled oscillators can proceed through regimes characterized by different relations between oscillation frequencies. A progressive increase of RTN/pFRG excitability as defined by the CO_2 level results in an emergence and subsequent increase in the frequency of its oscillations. Due to coupling between RTN/pFRG and BötC/pre-BötC oscillators, the system proceeds through a series of phase-locked resonances with 1: N ratios between the RTN/pFRG and BötC/pre-BötC frequencies, with N decreasing from an initial higher

Coupled Oscillations in Neural Control of Breathing, Fig. 5 The phase trajectories in the reduced model illustrating two synchronized late-E: pre-BötC states during hypercapnia (1:3 regime, *left panel*) and after suppression of pre-BötC (4:1 regime, *right panel*). The reduced model by Rubin et al. (2011) describes neural populations as two-dimensional relaxation oscillators with one fast and one slow variable. Fast variables V_2 and V_5 represent membrane potentials of early-I neuron in pre-BötC and late-E neuron in RTN/pFRG, respectively; m_2 and h_5 are slow

variables of these oscillators. Subthreshold activities of late-E neuron (*left*) and early-I neuron (*right*) are shown by *dashed lines*. Suprathreshold parts of trajectories (*solid lines*) correspond to bursts of the late-E (*left*) and pre-BötC (*right*) neurons. Cyclical subthreshold movement on the *left panel* indicates two periods of early-I activity during which the late-E neuron fails to burst. Similar movement on the *right* shows four late-E oscillations during which pre-BötC neurons fail to activate (Adapted from Rubin et al. (2011) with permission)

value to 1 ($N = 3$ on Fig. 5). The specifics of this coupling define a phase (late-E) of RTN/pFRG oscillations in all synchronized states.

In contrast, progressive suppression of pre-BötC excitability (e.g., by opioid agonists) results in a decrease in frequency of BötC/pre-BötC rhythm generator and ultimately in cessation of its oscillations. In this regime, the pre-BötC neurons depend on recruitment by the late-E neuron to activate. Because of this coupling, the pre-BötC frequency is quantally reduced through a series of resonances with M:1 ratios between the RTN/pFRG and BötC/pre-BötC frequencies with M increasing from 1 to higher values (see $M = 4$ on Fig. 5).

Definition

Current source density analysis (CSD) is a class of methods of analysis of extracellular electric potentials recorded at multiple sites leading to estimates of current sources generating the measured potentials. It is usually applied to low-frequency part of the potential (called the local field potential, LFP) and to simultaneous recordings or to recordings taken with fixed time reference to the onset of specific stimulus (evoked potentials, EP).

Detailed Description

Among the different mechanisms contributing to extracellular electric potential in the tissue (Buzsáki et al. 2012; Einevoll et al. 2012), trans-membrane currents in neurons are believed to

dominate. These are ionic currents passing through all the different membrane channels (passive, voltage dependent, calcium dependent, synaptic, etc.) as well as the capacitive currents which, while charging the membrane, also contribute to the motion of ions in the extracellular space, influencing the extracellular potential and seen by the extracellular electrode. The places where net current is entering or leaving the cell are called *current sources or sinks*. While these sources are localized along the membrane of the neuron, in practice, with a finite resolution afforded by available electrode setups and limited by typical densities, we may only recover coarse-grained density. This is what we have in mind when discussing estimation of current source density. Figure 1 shows the relation between the “microscopic” currents (a), coarse-grained field we usually have in mind (b), and a

reconstruction of the CSD from measured potentials (c).

CSD analysis can be performed for signals in full spectrum or in any selected band, although it is usually applied to the low-frequency part (<500 Hz) of the extracellular potential (LFP). We propose here such an expansion of LFP as the commonly used term local field potential is actually a misnomer, since due to the long-range nature of the electric field, LFP can be observed millimeters away from sources (e.g., Kajikawa and Schroeder 2011; Lindén et al. 2011; Hunt et al. 2011; Łęski et al. 2013). Despite that filtering in frequencies, it is known that fast processes, such as spikes, may still contribute to the LFP (Buzsáki et al. 2012; Einevoll et al. 2012; Reimann et al. 2013).

When net positive current enters the cell, we speak of current sink, and it corresponds to

Current Source Density (CSD) Analysis, Fig. 1 Comparison of the current sources obtained in a simulation (a) with coarse-grained CSD (smoothed with a Gaussian kernel of $\sigma = 75 \mu\text{m}$) (b) and a reconstruction with kernel CSD method (c) from LFP computed at a grid of 8×14 electrodes from the data in (a). Data were taken from the cortical part of a simulation of 3500 cells in the

model of thalamocortical loop based on Traub et al. (2005), 10 ms after simulated thalamocortical stimulus. Dominating contributions to CSD come from infra- and supragranular pyramidal cells. Vertical distance given in μm from cortical surface, horizontal from the center of the simulated column (H. Głabka)

negative CSD. When net negative current enters the cell, we speak of current source, and it corresponds to positive CSD. Since negative CSD is observed for excitatory synaptic stimulation (positive current entering the cell/negative CSD), many researchers prefer to denote current sinks by red (“hot spot”) and current sources by blue. There are a comparable number of researchers who prefer to do the opposite, according to the sign of CSD (red for positive, blue for negative). This situation has led to two opposite conventions being in wide use. A reader is advised to always check carefully what is the convention used in a given work.

Physics Behind the Relation Between the CSD and LFP

To get intuitive understanding of the basic relation between current sources and extracellular potential, consider infinite, homogeneous, and isotropic conductive medium of conductivity σ (Tranquillo 2008). If we place a stimulating electrode and inject current I , it will induce current flow in the tissue with current density $\vec{J} = I\hat{r}/(4\pi r^2)$ radially at a distance r away from the stimulation point (Fig. 2).

In a purely conductive medium, Ohm’s law holds $\vec{J} = \sigma\vec{E} = -\sigma\nabla V$, which gives us the potential in space $V(r) = I/(4\pi\sigma r)$. A multitude of currents I_j located at $\vec{r}_j$ induce potential $V(\vec{r}) = \sum_j I_j / (4\pi\sigma |\vec{r} - \vec{r}_j|)$. It is natural to introduce *current source density (CSD)*, $c(\vec{r}) = \sum_j I_j \delta(\vec{r} - \vec{r}_j)$, a scalar density field which is usually coarse grained to a smooth quantity (see Fig. 1). With this definition we get the relation between the CSD and the potential as

$$V(\vec{r}) = \frac{1}{4\pi\sigma} \int d^3\vec{r}' \frac{c(\vec{r}')}{|\vec{r} - \vec{r}'|} \quad (1)$$

or inverting this relation, we obtain the Poisson equation

Current Source Density (CSD) Analysis, Fig. 2 Current I injected at the origin of the system spreads uniformly in all directions in infinite, homogeneous, and isotropic medium

$$C(\vec{r}) = -\sigma\Delta V \quad (2)$$

Equations (1) and (2) are valid only in our restricted setting. Equation (2) can be generalized for arbitrary conductivity tensor fields σ :

$$C(\vec{r}) = -\nabla \cdot [\sigma \nabla V] \quad (3)$$

Solving Eq. (3) usually requires numerical methods. Careful derivations of Eq. (3) can be found in (Nicholson 1973; Stevens 1966; Nunez and Srinivasan 2005).

Methods of CSD Estimation

The simplest numerical approximation to the Laplacian is the three-point formula

$$\begin{aligned} C(x_k, y_l, z_m) \approx & -\sigma [V(x_{k+1}, y_l, z_m) \\ & - 2V(x_k, y_l, z_m) + V(x_{k-1}, y_l, z_m) + V(x_k, y_{l+1}, z_m) \\ & - 2V(x_k, y_l, z_m) + (x_k, y_{l-1}, z_m) \\ & + V(x_k, y_l, z_{m+1}) - 2V(x_k, y_l, z_m) \\ & + V(x_k, y_l, z_{m-1})] / \delta^2 \end{aligned}$$

which was introduced by Pitts (1952). While in the original application two-dimensional case was considered, by far the most common use of this approach has been in the study of one-dimensional cortical recordings with linear multi-electrodes. One then considers lateral invariance of the potential as a consequence of laminar structure of the cortex keeping a single term in the above formula. This approach has been made popular in the early 1970s by work of Haberly and Shepherd (1973) and especially Nicholson and Freeman (1975). Much of the work in this area till 1985 has been summarized by Ulla Mitzdorf in her still very useful review (1985).

We refer to this approach as the *traditional CSD (tCSD) method*.

Methodologically, there have been few advances in the estimation of CSD from the measurements since Pitts work till 2006. The main deficiencies of the traditional approach are lack of control over the assumptions made, such as extent of the sources in the dimensions which are not probed and between the contacts, spatial and measurement noise, and the necessity of exclusion of contacts at the border. To reduce the noise, Rappelsberger et al. (1981) proposed to smooth the measurements with a Hamming window obtaining a five-point formula in 1D

$$C(z) = -\sigma[0.23V(z - 2\delta) + 0.08V(z - \delta) + 0.08V(z + \delta) + 0.23(z + 2\delta)]/\delta^2$$

which gained some popularity. In 1988, Vaknin et al. proposed to extend the grid of electrodes beyond the actual set of contacts copying the outmost recordings to the added contacts. While in general physically questionable, this numerical trick allowed computation of CSD values for all contact positions and was used in cortical studies.

Rapid development of new multielectrodes at the beginning of the twenty-first century (Egert et al. 1998; Csicsvari et al. 2003; Buzsáki 2004; Berdondini et al. 2005; Kipke et al. 2008; Frey et al. 2009) stimulated renewed interest in LFP recordings and analysis, including CSD analysis. In 2006, Pettersen et al. proposed a new, model-based approach to CSD estimation, which they termed *inverse CSD (iCSD) method*. The method was later generalized to three- and two-dimensional regular recording setups (Łeński et al. 2007, 2011).

The idea behind iCSD is to assume a parametric model of the sources of as many parameters as the number of measurements. For example, for measurements of potential $V_1, \dots, V_N$ at points $\vec{x}_1, \dots, \vec{x}_N$, we may take the values of CSD at measurement points $C_1, \dots, C_N$ as parameters and spline interpolate in between (*spline iCSD*). Then

$$C(\vec{x}) = \sum_{k=1}^N C_k f_k(\vec{x}), \text{ where } f_k(\vec{x}) \text{ is a}$$

function taking 1 at $\vec{x}_k$, 0 at $\vec{x}_{l \neq k}$, and spline interpolated in between. From such a model, one can compute potential at the measurement points using forward modeling formula, Eq. 1. This leads to a matrix relation between the potential and the CSD given by $V_j = \sum_k M_{jk} C_k$, where

$$M_{jk} = \frac{1}{4\pi\sigma} \int d^3\vec{x}' \frac{f_k(\vec{x}')}{|\vec{x}'_j - \vec{x}'|}$$

In lower dimensionality (1D, 2D), where one does not probe all directions, it is necessary to make assumptions about source behavior there. For example, in 1D one may assume invariance of CSD on disks of some radius R (e.g., of the size of cortical column) orthogonal to the shaft, and in 2D one may assume constancy or Gaussian decay of the source on an interval orthogonal to the MEA plane. These assumptions lead to other forms of matrix elements which incorporate the specific form of the model (Pettersen et al. 2006; Łeński et al. 2011).

For typical recordings the matrix relation between the LFP and CSD can be inverted leading to a formula for C_k as a function of measured potential, $\vec{C} = M^{-1}\vec{V}$, and in consequence to an estimate of current sources in the whole probed

region. A convenient feature of iCSD method is that the matrix M^{-1} is estimated once for a given setup and model of sources. Also, one can easily incorporate different boundary conditions overcoming naturally this limitation of the traditional approach (Łęski et al. 2007).

Inverse CSD is a framework which allows one to incorporate different assumptions about the structure of the sources or the properties of the tissue, e.g., its conductivity (Goto et al. 2010). An interesting variant was developed for localization of single-cell current sources during action potential generation (*spike CSD*, **sCSD**, Somogyvári et al. 2005, 2012). The flexibility of the framework is in the construction of the function space used for estimation. However, iCSD was developed for regular recording grids and under the assumption of negligible recording and position noise, which could not be easily overcome within this framework.

A general solution to these problems was provided with *kernel current source density (kCSD) method* (Potworowski et al. 2012). While in iCSD the dimension of the function space in which one does estimation is equal to the number of measurements, in kCSD one constructs spaces of much larger dimensionality. The flexibility in tackling arbitrary electrode setups comes from separation of the construction of estimation space from the definition of the setup. The use of

kernel methods allows us to use standard techniques for dealing with noise (e.g., ridge regression, etc.) as described below.

Assume potentials $V_1, \dots, V_N$ measured at points $\mathbf{x}_1, \dots, \mathbf{x}_N$. To construct the framework of kCSD, we start with two linear spaces: the space of sources

$$\tilde{\mathcal{F}} = \left\{ C(\mathbf{x}) = \alpha_1 \tilde{b}_1(\mathbf{x}) + \dots + \alpha_M \tilde{b}_M(\mathbf{x}) : \tilde{b}_i : \mathbb{R}^d \rightarrow \mathbb{R} \right\},$$

and the space of potentials

$$\tilde{\mathcal{F}} = \left\{ V(\mathbf{x}) = \alpha_1 b_1(\mathbf{x}) + \dots + \alpha_M b_M(\mathbf{x}) : b_i : \mathbb{R}^d \rightarrow \mathbb{R} \right\},$$

with the dimension of the spaces, M , much greater than the number of measurements, N . The basis functions are related by a linear operator $\mathcal{A} : \tilde{\mathcal{F}} \mapsto \mathcal{F}$ so that $b_i = \mathcal{A} \tilde{b}_i$, and $V(\mathbf{x}) = \mathcal{A} C(\mathbf{x}) =$

$\sum_{i=1}^M \alpha_i b_i(\mathbf{x})$. In three dimensions (isotropic, homogeneous) $\mathcal{A} = -\sigma \Delta$, in lower dimensionality, we must assume properties of the sources in the directions not probed for the same reasons as in iCSD. For instance, if in 2D we assume that the sources are invariant in the direction z orthogonal to the electrode plane (x, y) within a layer of $2h$, then the physical $CSD(x, y, z)$ is $C(x, y)$ for $|z| < h$ and 0 otherwise, and

$$b_i(x, y) = \mathcal{A} \tilde{b}_i := \frac{1}{2\pi\sigma} \int dx' \int dy' \arcsinh \left(\frac{h}{\sqrt{(x-x')^2 + (y-y')^2}} \right) \tilde{b}_i(x', y')$$

We require that b_i ($\tilde{b}_i$) are linearly independent and so they constitute bases of the linear spaces $\tilde{\mathcal{F}}$ and $\mathcal{F}$. To efficiently estimate in such a large space, we construct a kernel function

$$K(\mathbf{x}, \mathbf{x}') = \sum_{i=1}^M b_i(\mathbf{x}) b_i(\mathbf{x}'),$$

which introduces the structure of reproducible kernel Hilbert space (RKHS) on $\mathcal{F}$ (Aronszajn

1950). Using representer theorem from RKHS theory (Schoelkopf and Smola 2002), one can show that minimum estimation error

$$err(V(\cdot)) = \sum_{i=1}^N (V(x_i) - V_i)^2 + \lambda \|\beta\|^2$$

is obtained for potential function of the form

$$V(\mathbf{x}) = \sum_{k=1}^N \beta_k K(\mathbf{x}_k, \mathbf{x}) \in \mathcal{F},$$

where

$$\begin{bmatrix} \beta_1 \\ \vdots \\ \beta_N \end{bmatrix} = \begin{bmatrix} K(\mathbf{x}_1, \mathbf{x}_1) + \lambda & \cdots & K(\mathbf{x}_1, \mathbf{x}_N) \\ \vdots & \ddots & \vdots \\ K(\mathbf{x}_N, \mathbf{x}_1) & \cdots & K(\mathbf{x}_N, \mathbf{x}_N) + \lambda \end{bmatrix}^{-1} \begin{bmatrix} V_1 \\ \vdots \\ V_N \end{bmatrix},$$

which can be written in more compact notation as

$$\boldsymbol{\beta} = (\mathbf{K} + \lambda \mathbf{I})^{-1} \cdot \mathbf{V}$$

with an obvious definition of terms. Having estimated the potential, we use the relation between the basis functions to construct a cross-kernel function:

$$\tilde{K}(\mathbf{x}, \mathbf{x}) = \sum_{j=1}^M b_j(\mathbf{x}) \tilde{b}_j(\mathbf{x})$$

with which the current sources estimated in the measurement space are given

$$\text{by } C * (\mathbf{x}) = \tilde{\mathbf{K}}^T(\mathbf{x}) \cdot (\mathbf{K} + \lambda \mathbf{I})^{-1} \cdot \mathbf{V} \quad \text{with} \\ \tilde{\mathbf{K}}^T(\mathbf{x}) := [\tilde{K}(\mathbf{x}_1, \mathbf{x}), \dots, \tilde{K}(\mathbf{x}_n, \mathbf{x})].$$

Parameter λ can be selected from data using, for instance, cross-validation. For further details on kCSD, see Potworowski et al. (2012). Figure 3 shows an example of CSD estimation with kCSD method.

Limitations of CSD Analysis

The main difficulty in the interpretation of CSD profiles is that it is not possible to tell without extra knowledge what is the nature of a given observed feature, for example, if a spot of negative CSD is due to excitatory synaptic stimulation or a passive return current matching inhibitory current elsewhere. Thus, one usually has to build on extra a priori knowledge of system's anatomy

Current Source Density (CSD) Analysis, Fig. 3 Example of source reconstruction with kCSD method. (a) Model sources shown were used to generate potentials at randomly selected electrode locations marked with black dots. (b) Potential interpolated from the

potential measured at the electrode locations. (c) CSD reconstructed from the random 16 measurements. (d–f) Sources reconstructed from 2, 4, and 8 measurements, respectively

and physiology (Gratiy et al. 2011) or use computational models of the studied systems (Makarov et al. 2010; Potworowski et al. 2011). If possible, do both.

CSD analysis allows one to better localize neural activity by deconvolution of the inverse distance kernel. However, since usually multiple cell populations overlap, observed profile of the current sources will reflect summary activity of all of them. One way to overcome this problem is to use a method of source decomposition (see Einevoll et al. 2013, for a discussion). It seems that independent component analysis (ICA) following CSD gives functionally meaningful results (Łęski et al. 2010; Makarov et al. 2010; Potworowski et al. 2011).

To tackle both the problem of overlapping populations and unknown origin of the given source, it is particularly useful to generate ground truth data as close to the system studied as possible, for instance, from large-scale models (Potworowski et al. 2011; Reimann et al. 2013).

Finally, let us observe that all the CSD methods mentioned so far rely on Eq. (3) which has recently been challenged (see chapter Local Field Potentials: Interaction with the Extracellular Medium for a review). In that case the physical part of the CSD model must be modified (Bedard and Destexhe, Physical Review E 2011).

Cutaneous Mechanoreceptive Afferents: Neural Coding of Texture

Justin Lieber
Committee on Computational Neuroscience,
University of Chicago, Chicago, IL, USA

Definition

We can identify objects by the way they feel. As we move our fingers over objects in our pocket or purse, we can easily distinguish between our keys and our phone or between two different fabrics in our dresser drawer. The tactile perception of the surface texture of objects, i.e., of their microstructure and material properties, contributes to our ability to identify them by touch. Signals in the nerve convey information that allows us to identify different textures, as well as attribute different

perceptual properties (e.g., roughness or hardness) to them.

Detailed Description

Spatial and Temporal Mechanisms

When we run our fingers across a textured surface, a characteristic pattern of deformations is produced in the skin (Sripati et al. 2006), and the resulting stresses and strains are transduced by multiple populations of mechanoreceptors embedded in the skin. The spatial layout and timing of the consequent spatiotemporal patterns of afferent activation convey information about surface texture (Weber et al. 2013).

As coarse textural features indent the skin, their spatial layout is reflected in the spatial pattern of activation evoked across the population of Merkel disks, which are relatively dense in the fingertip skin and are innervated by slowly adapting type 1 (SA1) afferents (Johansson and

Vallbo 1979) (Fig. 1). SA1 afferents thus encode spatial patterns in a manner analogous to photoreceptors in the retina. SA1 responses are uniquely suited to transduce spatial features as they have small receptive fields; that is, they only respond to small and sharply defined patches of skin. SA1 responses are strongly modulated by spatial features like edges, corners, and indentation depth (Johnson 2001). The spatial image carried by SA1 afferents is further elaborated in the somatosensory cortex, where neural responses exhibit a sensitivity to spatial features like edges (Bensmaia et al. 2008; Phillips et al. 1988), curvature (Yau et al. 2013), and motion (Pei et al. 2010) in ways that draw strong analogies to their visual cortical counterparts.

Although the SA1 spatial image effectively relays information about coarse textural features, many tangible surface features are too fine to be resolved spatially, given that the skin filters out very fine features (Sripati et al. 2006; Weber et al. 2013). In fact, information about fine textural

Cutaneous Mechanoreceptive Afferents: Neural Coding of Texture, Fig. 1 SA1 spatial image. SA1 receptors carry a spatial pattern of information. (a) When *dot* patterns (*top*) are serially scanned over the finger, they elicit a spatial pattern of activation in example *SAI*, *RA*, and *PC*

receptors (Connor et al. 1990). (b) Examples of the *SAI*, *RA*, and *PC* response to letters serially scanned over the finger (Phillips et al. 1988). Note that the SA1 spatial image is characterized by well-resolved edges and corners (when compared to the RA and PC spatial images)

features is not perceptually accessible until the skin is actively scanned over a surface (Hollins and Risner 2000). Movement between a textured surface and the skin results in vibrations (Manfredi et al. 2014; Bensmaia and Hollins 2003, 2005) that reflect both spatially resolvable features as well as fine surface microgeometry. These vibrations elicit highly precise and repeatable temporal spiking patterns in rapidly adapting Meissner corpuscles (innervated by rapidly adapting or RA afferents) and Pacinian corpuscles (innervated by PC afferents). These patterns carry information about the skin vibrations (Talbot et al. 1968; Mackevicius et al. 2012) and thus about the texture itself (Weber et al. 2013; Fig. 2).

In summary, then, coarse textural features are encoded in the spatial pattern of activity evoked in one population of afferents – SA1 fibers – while

fine textural features are encoded in the temporal patterns of activity evoked in the other two, RA and PC fibers.

Multidimensionality of Texture Perception

The sensation of exploring a surface can be described along a number of perceptual dimensions: things may feel rough or smooth, hard or soft, sticky or slippery, and warm or cool (Hollins et al. 2000). The dominant dimension, and the most studied one, is roughness.

Roughness

Perceived roughness is determined by how variable the neural responses to textures are over time

Cutaneous Mechanoreceptive Afferents: Neural Coding of Texture, Fig. 2 The timing of PC responses encodes information about skin vibrations. (a) High-resolution surface profiles of natural texture stimuli. (b) Texture-specific responses by an example PC receptor. PC responses are precisely timed and repeatable. (c) Trial-by-

trial power spectra of PC responses. Textures may elicit sharply periodic responses from PC receptors. (d) The periodicity in PC responses (average power spectra, orange) matches the frequency of skin vibrations (black) (Weber et al. 2013)

and space. Specifically, the spatial variability across the SA1 population response (Fig. 3a; Connor et al. 1990; Connor and Johnson 1992; Blake et al. 1997) is integrated with the temporal variability in the response of RA and PC afferents (Fig. 3b, c; Weber et al. 2013) to culminate in a percept of roughness (Fig. 3d). In other words, a texture is perceived as rough to the extent that different SA1 afferents produce different responses and individual RA and PC afferents produce responses that change over time.

Sensitivity to peripheral variability is a common feature of sensory processing. Indeed, when stimuli do not change in time, central sensory neurons across all modalities adapt toward their

baseline level of activity (Wark et al. 2007). In this way, adaptation serves to increase neural sensitivity to variations in the sensory input. Furthermore, sensory neurons in both visual and somatosensory cortex exhibit both excitatory and inhibitory components and thus show sensitivity to spatial differences in activation across the sensory sheet.

Hardness

Judgments of surface hardness lie on a subjective continuum that closely covaries with measurements of surface compliance (Fig. 4a; Harper and Stevens 1964). Information from spatial patterns of afferent activation, response timing, kinesthesia, and even audition may be combined to culminate in a percept

Cutaneous Mechanoreceptive Afferents: Neural Coding of Texture, Fig. 3

Signals from multiple receptors types are necessary to explain roughness. (a) SA1 spatial variation is plotted against judgments of roughness for natural textures, including both coarse (plastic dots and gratings, green) and fine (fabrics and sandpapers, orange) textures. Error bars represent SEMs across subjects

(roughness) and neurons (variation). The gray line denotes the line of best fit. SA1 spatial variation barely changes across a fourfold scale in roughness for fine textures. (b and c) Temporal variation for RA and PC afferents, respectively, plotted against perceived roughness. (d) A combined model of all three predictors almost perfectly predicts texture roughness (Weber et al. 2013)

Cutaneous Mechanoreceptive Afferents: Neural Coding of Texture, Fig. 4 Hardness perception. (a) Judgments of hardness and softness covary closely with a measure of surface compliance (Harper and Stevens 1964). (b) Afferent activity in response to compliant stimuli indented into the skin. SA1 (*top*) and RA (*bottom*) responses are plotted against surface compliance

(numbered from the softest (1) to hardest (9) surface) for three different application forces. Both SA1 and RA afferents fire, while surfaces are actively loaded onto the skin (*left*), but only SA1 afferents fire when the surfaces are static (*right*). For a given force, firing rates increase with surface hardness

of hardness (Srinivasan and Lamotte 1995; LaMotte 2000). Thus, hardness perception involves a complex reconstruction of a measurable surface property but does not seem to be based on a simple readout of a singular neural quantity.

Information from both spatial and temporal mechanisms is combined to reconstruct judgments of hardness. Surfaces with different compliance lead to different spatial patterns of deformation of the skin: soft surfaces deform around the skin, while hard surfaces change the shape of the skin. These spatial patterns of skin deformations are reflected in the spatial patterns of activation elicited in populations of SA1 afferents (Franzén et al. 1996).

Precisely timed information can also be used to determine hardness. When judged through a probe, hardness is most effectively perceived using rapid tapping motions (LaMotte 2000), which elicit dynamic force profiles that most effectively recruit RA and PC afferents. Indeed, while SA1 responses to statically indented stimuli are informative about surface compliance, RA responses only convey hardness information during the dynamic loading phase (Fig. 4b; Condon et al. 2013).

Stickiness

Perceptual judgments of stickiness are often closely correlated with perceptual judgments of roughness (Hollins et al. 2000). When exploring the stickiness of a surface, subjects tend to apply a set amount of force normal to the surface. The resulting range of force tangential to the surface covaries closely with measurements of perceived stickiness (Smith and Scott 1996). Tangential forces stretch the skin, which excites Ruffini cylinders (innervated by slowly adapting type II (SAII) afferents) (Knibestol 1975) as well as SA1 and RA afferents (Birznieks et al. 2001, 2010).

Thermal Conductivity

Perception of a surface's temperature is clearly used for object identification (Katz and Krueger 1989) and is incorporated into the multidimensional percept of texture (Bensmaia and Hollins 2005; Hollins et al. 2000). Because everyday objects tend to be colder than skin temperature, surface temperature is determined by the rate of heat flow out of the skin (Ho and Jones 2006). This heat flow is almost certainly transduced by thermoreceptive afferents in the skin (Darian-Smith et al. 1973, 1979; Johnson et al. 1973, 1979).

Conclusion

Spatiotemporal patterns of activation across the four main populations of afferents that innervate the glabrous skin of the hand – SA1, RA, PC, and SAI – as well as thermoreceptors, convey exquisite and multidimensional information about surface texture. Different information about surface texture is conveyed in different aspects of afferent responses, with spatial patterns mediating the perception of coarse features and compliance and temporal patterns mediating the perception of fine features. Importantly, the perception of texture reflects the integration of different types of signals from multiple different tactile submodalities.

Cx3D: Cortex Simulation in 3D

Andreas Hauri

Institute of Neuroinformatics, ETHZ/UZH,
Zürich, Switzerland

Definition

Cx3D (pronounced Cortex 3D) is a simulation tool for simulating the growth primarily of neural tissue but is also capable of simulating other tissue growth. Cx3D allows a modeler to simulate the behavior of cells and their axonal and dendritic extensions in an artificial environment. Each cell can interact locally with its environment that consists of other cells and a chemical environment. The emphasis in Cx3D is on the local behavior of cells and the emergence of a global structure through the local behavior of the cells. It is not concerned with the simulation of an individual cell's internal environment but how multiple cells can organize themselves.

Detailed Description

In order to understand how tissue forms, and therefore how parts of the body of a multicellular organism form, we must study how cells organize themselves into these composites. Each cell is an individual; it has an internal environment of chemicals that is separated by a membrane from the external environment. The cell is the basic operational unit of an organism. In the development of an animal, each body starts with the

fertilized egg. The fertilized egg, a single cell, starts to divide and create more cells. With each cell cycle the number of cells potentially doubles, and thus, exponentially more cells are created over time. These cells form all the body parts, but how do they do this? There is no global controlling unit that tells each cell what to do. Each cell individually has to figure out what it has to do in this vast sea of potentially billions of other cells.

Cx3D is a simulation program that allows modelers to try out their theories of how the developmental process happens. Even though Cx3D was written with the intention of studying the development of neural tissue, it is not limited to that. Cx3D allows cells to divide, grow out axons and dendrites, secrete external and internal chemicals, read internal and external chemicals, and move around in the environment (the extracellular matrix which forms the biological environment of cells). The modeler has full control over these actions and can write small modules called *BiologicalModules* that are essentially programs running in the cells to define their behavior. *BiologicalModules* can be seen as an epiphenomenological model of proteins working together that define one behavior of a cell, e.g., to move the cell in a direction defined by an extracellular chemical gradient.

Cx3D provides a basic physics engine that prevents cells and cell parts from overlapping. The user of the simulation tool does not have to worry about the detailed implementation of the physical processes if he does not want to do so and can focus on the biological aspects of the model. In order to support the modeler even further, a language has been developed that supports the modeler in only allowing biologically plausible commands for the cells. This language, named *GCode*, is not directly part of Cx3D and therefore does not have to be used, but it proves to be very helpful in developing correctly behaving models.

In Cx3D, the cells are compartmentalized. The soma is approximated with a sphere, and the axons, dendrites, and other processes are approximated with cylinders. Each of these compartments can potentially run a different *BiologicalModule* and therefore have a biologically active behavior.

They are all passively subject to the force scheme of the simulation tool.

Cx3D operates on three levels of simulation: a biological, a physical, and a spatial level. The spatial level provides the neighborhood relations between the different compartments of the cells. The physical level uses the spatial information to calculate forces between the cellular compartments and takes care of intracellular and extracellular chemical diffusion processes. The biological level makes use of the physical level and organizes the compartments into cells that can run BiologicalModules. The simulation is round based and approximates development in small time steps.

Since tissue is built of thousands and potentially millions of cells, Cx3D has been extended into Cx3Dp (p for parallel) that runs in a multi-core/multi-computer environment to allow for these big simulations.

More information on Cx3D, along with links to publications and the latest version of the source code, can be found at <http://www.ini.uzh.ch/~amw/seco/cx3d>.

Decision Making, Countermanding Oculomotor Models

Vassilis Cutsuridis

School of Computer Science, University of Lincoln, Lincoln, UK

Definition

The countermanding oculomotor task or stop-signal task (see Fig. 1) requires participants to make a saccade to a GO stimulus (*no-stop-signal* trial) but stop the saccade when a STOP signal is presented (*stop-signal* trial). Participants' ability to inhibit the response depends on the interval between the GO and STOP signals, often referred to as the *stop-signal delay* (SSD). When the GO signal has a small head start relative to the STOP signal, then subjects succeed at inhibiting their responses. As the head start grows, subjects often fail to inhibit the response.

Detailed Description

The Countermanding Oculomotor Task

The countermanding saccade task (Fig. 1) is a response inhibition paradigm, in which participants are required to make a saccade as quickly

as possible to a GO signal (*no-stop-signal* trial). In few trials a STOP signal is presented, and the response must be stopped (*stop-signal* trial). There are two possible behavioral outcomes in this paradigm: (1) Participants fail to inhibit their response producing a *signal-respond* trial with a signal-respond reaction time (RT) and (2) participants inhibit their response producing a *signal-inhibit* or cancelled trial. Participants' ability to inhibit their response depends on the interval between the GO and STOP signal presentation, often referred as the *stop-signal delay* (SSD) (see Fig. 2a). When SSD is short, subjects often succeed at inhibiting; as SSD grows, subjects often fail to inhibit the response. When subjects fail to stop on stop-signal trials, their responses tend to be faster than on trials without a stop signal. An important aspect of the countermanding task is to determine the *stop-signal reaction time* (SSRT), the length of time required to cancel the saccade being programmed and maintain fixation on the central fixation spot. Because the duration of this inhibitory process is not explicit in the behavioral data, then an estimate of SSRT is calculated as the mean reaction time when no-stop signal is given minus the delay for which inhibition occurs on 50% number of trials (Hanes and Carpenter 1999). The probability of inhibiting/probability of responding as a function of SSD is referred as the inhibition function (see Fig. 2b for the probability of responding as a function of SSD).

Decision Making, Countermanding Oculomotor Models, Fig. 1 Basic design of the countermanding task. (Reproduced with permission from Hanes and Carpenter (1999), Fig. 1, p. 2778, Copyright © 1999, Elsevier). Typically a participant fixates on a central fixation spot (F) for a variable interval. Once it disappears, a visual target (T) simultaneously appears in the periphery.

After a delay in some trials, the fixation spot may reappear (stop-signal delay (SSD)) during which subjects are instructed to withhold the movement. Subjects sometimes successfully countermand the saccades, and sometimes they do not. The dotted circle indicates the focus of gaze at each interval, and the arrow indicates the saccade

Decision Making, Countermanding Oculomotor Models, Fig. 2 (a) Schematic indicating how the probability of responding [$p(\text{respond}|\text{signal})$] and the probability of inhibiting [$p(\text{inhibit}|\text{signal})$] depend on GO- RT, SSD, and SSRT distributions. Human Performance in the Countermanding Oculomotor Task

Early countermanding or stop-signal experiments involved manual responses to visual GO signals and visual/auditory STOP signals (Logan and Cowan 1984). The first countermanding oculomotor task was introduced by Hanes and Carpenter (1999). In this task, participants were asked initially to fixate on a central stimulus. As soon as the central (fixation) stimulus disappeared, a peripheral (target) stimulus appeared either to the left or right peripheral visual field, and the participants had to make a saccadic eye movement toward it. On some trials, the fixation stimulus reappeared, acting as a STOP signal, instructing the participant that the saccade should be inhibited and instead to hold his/her gaze on the fixation stimulus. Mean saccade latencies on the GO trials were reported to be 200–300 ms and were faster with a higher luminance contrast visual stimulus. On the other hand, SSRTs ranged from 125 to 145 ms but did not vary with target luminance. Schall and Thompson (1999) suggested that the short STOP signal latency may be due to the STOP signal being presented centrally to the fovea. Asrress and Carpenter (2001) tested the effectiveness of central and peripheral visual stimuli in the stop-signal response. They reported that central and peripheral visual stop cues produced the same SSRTs. However, when both cues were used, then the SSRTs were shortened, suggesting that the central and peripheral stop signals have independent inputs to the stopping process.

Other experiments examined the effects of other sensory modalities in response inhibition and reported that the SSRTs were slightly longer when an auditory or a tactile instead of a visual stimulus was used as a STOP signal (Armstrong and Munoz 2003; Morein-Zamir and Kingstone 2006; Akerfelt et al. 2006; Cabel et al. 2000). Subsequent experiments have reported that human subjects respond faster and with greater accuracy to stimuli that are brighter, louder, and associated with larger reward or have larger

probability of appearance, than to neutral stimuli (Wattiez et al. 2016).

Recent experiments investigated how saccade cancellation is influenced by the fixation disengagement (Stevenson et al. 2009). Human participants performed countermanding experiments that required them to try to cancel an impending saccade in the presence of an imperative visual STOP signal, across different fixation conditions. Stop signal reaction times were ~40 ms shorter on trials with a 200 ms gap between fixation point removal and target presentation compared with when the fixation point remained illuminated. Investigators concluded that the reduction in SSRTs were primarily due to removal of a foveal fixation point (as opposed to a generalized warning effect) and persisted with an auditory stop signal that controlled for potential differences in stop signal saliency across different fixation conditions.

Countermanding Oculomotor Performance in Disorders

Countermanding performance has also been investigated in many neurological and psychiatric disorders including attention deficit hyperactivity disorder (ADHD; Armstrong and Munoz 2003; Hanisch et al. 2006), schizophrenia (Thakkar et al. 2011, 2015), bipolar disorder (Thakkar et al. 2015), and Parkinson's disease (Farooqui et al. 2011).

In particular, patients with ADHD involved in a countermanding saccade task (Armstrong and Munoz 2003) made more impulsive eye movements than age-matched controls. Furthermore, ADHD participants were faster to respond to a target, but they were more likely to fail to countermand an eye movement on STOP trials (Armstrong and Munoz 2003). SSRTs of adult ADHD patients were reported to be longer in a saccadic countermanding task, particularly with an auditory or peripheral visual stop signal (Armstrong and Munoz 2003). Slower SSRTs were also observed in children diagnosed with ADHD (Hanisch et al. 2006).

Similarly, patients suffering with schizophrenia (Thakkar et al. 2011) were associated with increased latency to inhibit a planned saccade. Longer SSRTs were found in patients, despite patients having equal sensitivity to the stop signal and similar latencies to initiate a saccade. Their SSRTs were correlated with increased negative symptoms and poorer occupational functioning, indicating the clinical relevance of these findings. Patients made appropriate RT adjustments after errors but slowed down significantly more than control subjects after correctly inhibited saccades. Subsequent experiments from the same group tested the countermanding performance of schizophrenia patients in a double-step task (Thakkar et al. 2015). In this task, participants were required to make a saccade to a visual target. Infrequently, the target jumped to a new location, and participants were instructed to rapidly inhibit and change their response. Patients had poorer efficiency of inhibition, indexed by longer TSRT (target step reaction time). An impairment in response execution was also observed when patients were required to redirect gaze to a new location.

Non-human Primate Performance in the Countermanding Oculomotor Task

The primate brain circuits involved in the countermanding oculomotor task are complex, involving many brain areas (for reviews see Schall and Godlove (2012)). Neurons in the frontal eye field (FEF), supplementary eye field (SEF), lateral intraparietal area (LIP), pre-supplementary motor area (preSMA), and subthalamic nucleus (STN), and superior colliculus have been described as movement-related in the saccade countermanding task. However, neuronal recordings from SEF, LIP, preSMA, and STN have produced conflicting results (for more details see Stuphorn et al. 2000; Scangos and Stuphorn 2010; Isoda and Hikosaka 2007, 2008). The two brain areas that are the most studied and have produced the most consistent results in response inhibition in the countermanding task are the FEF and SC.

FEF is an area in the dorsolateral prefrontal cortex of macaque monkeys where neurons respond to visual stimuli but also are involved

in the production of saccadic eye movements (Bruce et al. 1985; Hanes and Schall 1996; Sommer and Wurtz 2000; Segraves and Goldberg 1987). The FEF movement-related neurons have been shown to discharge before and during saccades (Bruce and Goldberg 1985; Hanes and Schall 1996) and innervate other movement-related neurons in SC and the brainstem (Segraves and Goldberg 1987; Sommer and Wurtz 2000; Segraves 1992). Other FEF and SC neurons have been shown to discharge during fixation but suppress their activities during saccades. These fixation cells are critical for controlling saccade initiation. Electrical stimulation of SC fixation cells can interrupt saccades in monkeys (Gandhi and Keller 1999), and their deactivation results in excessive saccade initiation (Munoz and Wurtz 1993). Two experimental studies have described the activities of movement-related and fixation neurons in FEF and SC in macaque monkeys performing a saccade stop signal task (Hanes et al. 1998; Pare and Hanes 2003). Once the GO signal was given (target appeared), then movement-related neuronal activity in both areas grew toward a threshold. In trials where no STOP signal was presented, these activities continued to grow (see Fig. 3a left). The activities of corresponding fixation neurons were decreased (see Fig. 3a right). If a STOP signal was presented (*cancelled trial*), then the movement-related activities were inhibited (see Fig. 3a left) and the fixation cells generated rapid bursts (see Fig. 3a right). This activation reciprocity of movement-related and fixation cells naturally reinforces the idea that they share a mutually inhibitory relationship.

A similar inhibitory relationship exists between fixation and saccade neurons in macaque monkeys performing the antisaccade task (Everling et al. 1999; Everling and Munoz 2000). Fixation cells are tonically active when subjects are fixating, and they pause their activities when a saccade is executed. Saccade neurons, on the other hand, discharge when a saccade is initiated but remain silent during fixation. Two populations of saccade neurons have been recorded in SC: buildup and burst cells (Munoz and Wurtz 1993, 1995a, b).

Decision Making, Countermanding Oculomotor Models, Fig. 3 Normalized activity of FEF gaze-shifting (left) and gaze-holding (right) neurons. (Reproduced with permission from Schall and Godlove (2012), Fig. 2, p. 1014, Copyright ©, Elsevier). Thick green and red lines represent the activities of cancelled FEF gaze-shifting and gaze-holding neurons, respectively. Thin green and red

lines represent the activities of non-cancelled FEF gaze-shifting and gaze-holding neurons, respectively. Presentation of the stop signal is indicated by the solid vertical line. The time needed to cancel the planned movement – stop signal reaction time (SSRT) – is indicated by the dashed vertical line

Computational Models of Countermanding Oculomotor Performance

Over the years many mathematical and computational models of countermanding oculomotor performance have been proposed. Some of these models provide explicit descriptions of the mental processes that are tightly linked to countermanding behavior, and others focus on the neurons, networks, or brain regions involved in the countermanding task. A direct comparison of the performance of these various computational models in the countermanding task can be found in Table 1.

Independent Horse-Race Model

The oldest and most successful model of the countermanding task is the “independent horse-race model” (Fig. 4; Logan and Cowan 1984). The model is intuitively simple consisting of two *independent* accumulators, a GO process and a STOP process, which race each other till a predefined threshold is reached by one process. If the GO process, initiated at GO stimulus onset, reaches the threshold first, then stimulus response is generated, and the trial ends; if the STOP process, initiated at the STOP stimulus onset,

reaches the threshold first, then the subject stops, and the trial ends. The STOP process wins the race if $SSRT + SSD$ is less than the GO-RT. Then, the response is inhibited and a signal-inhibit trial takes place. If the $SSRT + SSD$ is greater than the GO-RT, then the GO process wins, the response is executed, and a signal-respond trial occurs. Because the GO-RT and SSRT are assumed in the model to be independent random variables drawn from their response time distribution, then the outcome of the race includes a random component. Increases in SSD favor the GO process and so the STOP process wins less often. Thus, the probability of inhibiting the response decreases, and the probability of responding increases. Such a relationship reproduces the experimentally observed inhibition function. The “independent race model” explains further why the responses in the stop-signal trials are faster than the no-stop-signal ones and how they change in relation to the SSD. When the SSD is short, only the fastest GO-RTs are faster than $SSRT + SSD$, so signal-respond RT is very short, reflecting the lower tail of the GO-RT distribution. As the SSD increases, more GO-RTs are fast enough to win the race, so signal-respond RT increases. If the SSD is long enough, all GO-RTs will win the race, and signal-respond RT will

Boosted-fixation 1.0 model (Logan et al. 2015)	√	√	√	√	√	

approach no-stop-signal RT. The model has been successfully able to quantitatively simulate the inhibition function as a function of SSD and the SSRT distributions across age, patient groups, and experimental conditions. The model did not though consider the underlying neural processes. Furthermore, recent experimental evidence has ruled against the independent race of the GO and STOP processes (Montagnini and Chelazzi 2009).

Countermanding LATER Model

A model similar to Logan and Cowan’s (1984) “independent horse-race model” is the countermanding LATER model of Hanes and Carpenter (1999) (see Fig. 5). The countermanding LATER model consists of two independent LATER units, a GO unit and a STOP unit, racing each other to a threshold. The rate of rise of each LATER unit’s activity takes values from two normal distributions with different means and standard deviations. In the model, as in the experiment, the GO

unit is activated first, followed by activation of the STOP unit, which in turn inhibits the GO unit. If the GO unit reaches the threshold before the STOP unit, then a GO response is generated. If the STOP unit reaches the threshold before the GO unit, then a No-GO response is generated. If the GO unit activity reaches threshold first, then a GO response is generated. The model is able to simulate accurately the RT distribution and inhibition function as a function of SSD. However, it does not attempt to provide any insights to the neural mechanisms of stopping.

Interactive Race Model

The “interactive race model” (see Fig. 6) was introduced (Boucher et al. 2007) as an alternative to the previous race models in order to suggest how neural circuitry could give rise to the observed behaviors. To this end, the authors (Boucher et al. 2007) quantitatively simulated the behavior of the countermanding task and

Decision Making, Countermanding Oculomotor Models, Fig. 4 Basic schematic of the independent horse-race model of countermanding performance. Two independent processes race toward a threshold, where one process is initiated by a GO signal, while the other process by a STOP signal after a variable stop signal delay (SSD). If the GO process crosses the threshold first, it wins the race and a non-cancelled response is made. If the STOP

process crosses the threshold first, it wins the race, and the response is inhibited. The STOP signal response time (SSRT) is the time between STOP signal onset and the point where the STOP process crosses the threshold to countermand the response. (Reproduced with permission from Hanes and Carpenter (1999), Fig. 4, p. 2782, Copyright ©, 1999, Elsevier)

Decision Making, Countermanding Oculomotor Models, Fig. 5 Countermanding LATER model. (Reproduced with permission from Noorani (2014), Fig. 4, p. 3, Copyright ©, Frontiers publishing company). A GO unit competes with a STOP unit, and the winner of

the competition determines the outcome. In some trials, the GO unit reaches threshold even in the presence of the STOP unit, which failed to stop it (non-cancelled trials). In other trials, the STOP unit is faster than the GO unit, so no response (saccade) is generated (cancelled trials)

specified the neural underpinnings of stopping. They proposed that lateral inhibition between competing neural accumulators is the mechanism for stopping. This model assumption was in line with the experimentally observed modulation of neural activity from recurrently inhibited neurons in SC and FEF, two brain areas directly

involved in saccadic eye movements (discussed in the previous section; Hanes et al. 1998; Pare and Hanes 2003). As in the previous models, the interactive model consisted of two accumulators, the GO process and the STOP process. The GO process was modelled as a stochastic accumulator that integrated neural activity over time until it

Decision Making, Countermanding Oculomotor Models, Fig. 6 Interactive race model. (Reproduced with permission from Logan et al. (2015), Fig. 9b, p. 49, Copyright © 2015 American Psychological Association)

reached a threshold, after which a response was made. Similarly, the STOP process was modelled as a stochastic accumulator that stopped the response by inhibiting the GO activation and preventing it from reaching the threshold. The STOP and GO processes were mutually inhibiting each other, but their strengths were asymmetric with the STOP process inhibiting the GO process more than the GO process inhibited the STOP process. Because in the model the GO and STOP processes proceed independently for most of their duration, the STOP unit inhibited the GO unit strongly only very late in the trial. This produces finishing times that appear independent, as in the independent model. The model has been successful at simulating accurately both behavioral and neurophysiological data including the activation profiles of gaze-responding neurons (movement and fixation cells) in the signal-inhibit and no-stop-signal trials.

Cancellable Rise-to-Threshold Model

Salinas' and Stanford's (2013) "cancellable rise-to-threshold model" is built on the foundation of the compelled saccade task (Shankar et al. 2011), which attempts to separate the contribution of perceptual and motor processing in the countermanding task. As in the interactive race model, programming a saccade involves a process

building activity to a threshold. The model assumes that once a stop-stimulus is presented, a perceptual mechanism detects it with a particular speed and reliability. Once the signal is detected, then the movement plan decelerates, and the movement is stopped. The model successfully replicates the experimentally observed countermanding behavior, but it does not attempt to reproduce the recorded neural activity. However, it has been suggested to be profoundly similar to the "interactive race model" and hence matches the earlier model in its predictions (see Bissett (2013) for a critique of the "cancellable rise-to-threshold model").

Augmented Interactive Race with Pre-target Input Model

Wong-Lin and colleagues (2010) advanced an extension (see Fig. 7) of the "interactive race model" by including an additional pre-target input to account for the experimentally reported high firing rates of fixation neurons (Hanes et al. 1998). They demonstrate that such simulated pre-target fixation neuronal activity reproduces countermanding behavior that maximizes reward rate as a function of SSD, fraction of stop-signal trials, intertrial interval, duration of timeout, and relative reward value. Further, it simulated accurately the neural traces of movement and fixation cells in no-stop and cancelled trials.

Spiking Interactive Race with Top-Down Inhibition Control Model

Lo and colleagues (2009) introduced an attractor-based model of neural spiking dynamics. The neural network model was multi-modular consisting of a premovement module that controlled inhibition of movements and a control module that provided a top-down inhibitory control over the premovement module. The model replicated the probability of responding and RTs on correct and error trials as well as the patterns of activity observed in SC and FEF (Hanes et al. 1998; Pare and Hanes 2003). The model made new predictions and suggested new experiments. Particularly, their model predicted that the neural activities of movement and fixation neurons are negatively correlated earlier in

Decision Making, Countermanding Oculomotor Models, Fig. 7 (Left) Augmented interactive race with pre-target input model. (Reproduced with permission from Wong-Lin et al. (2010), Fig. 1A, p. 12, Copyright © 2010 Elsevier Science Ltd). Asymmetrical mutual inhibition

between movement (MN) and fixation (FN) neural units is observed. (Right) Inputs trace to MN (green) and FN (red). SSD = stop signal delay. Cognitive control is assumed to vary pre-target FN input

non-cancelled trials than in cancelled trials. It demonstrated that inhibitory control in the countermanding task is due to modulation of the strength of the top-down drive to the movement module. Weaker simulated top-down control resulted in shorter reaction times, more errors, but unchanged SSRTs.

Despite its successes, the model did not incorporate all of the brain circuits involved in control of saccades, omitting areas such as the supplementary frontal eye field (SEF), and anterior cingulate cortex (ACC). Furthermore, the model did not separate the stimulus-driven input and the top-down input to fixation neurons in order to assess their effects on inhibitory control (Asrress and Carpenter 2001).

Other Race Models

Recently, Logan et al. (2015) introduced new variations of the original interactive race model (Boucher et al. 2007), namely, the “blocked-input 1.0 race model,” the “blocked-input 2.0 race model,” and the “boosted-fix 1.0 race model” (see Fig. 8). The “blocked-input 1.0 race model” assumed that the STOP unit did not directly inhibit the GO activation, but instead it activated a top-down process that turned off the GO activation and set the mean neural GO activity to zero once it reached the threshold. If the input is blocked early enough, then the GO neural activation did not reach the threshold and the response was inhibited. If the GO activation reached the

threshold before its input was blocked, then inhibition failed and the GO response was executed. The “blocked-input 1.0 race model” fits the behavioral data as well as the original interactive model indicating that direct inhibition from the STOP process on the GO process is not needed to account for the countermanding behavior. The “blocked-input 1.0 race model” fitted monkey neurophysiological data better than the original interactive model by predicting growth rates, decay rates, and cancel times that fell within the 95% confidence intervals of the observed monkey data. The “blocked-input 2.0 race model” was the same as the original interactive model with mutual inhibition between the GO and STOP processes except that it also includes a third independent top-down process that also inhibits the GO signal. Version 2.0 of the “blocked-input race model” produced as good a fit to the behavioral and neurophysiological data as version 1.0 but a better one than the original interactive model. The “boosted-fix 1.0 race model” assumed the presence of a similar top-down process, but which boosted the STOP activation instead of blocking the GO activation. It produced as good a fit to the data as the “blocked input 2.0 race model.” Further neurophysiological experimentation will show if such a hypothesized top-down signal that blocks the GO activation and/or boosts the STOP activation really exists and what mechanisms allow it to switch modes of operation.

Decision-Making Tasks

Angela J. Yu

Department of Cognitive Science, University of California, La Jolla, CA, USA

Definition

A diverse repertoire of behavioral tasks has been employed to examine the cognitive processes and neural basis underlying decision-making in humans and animals. Some of these have their origins in psychology, others in cognitive

neuroscience, yet others in economics. There is also a continual invention of novel or hybrid paradigms, sometimes motivated by deep conceptual questions stimulated by computational modeling of decision-making and sometimes motivated by specific hypotheses related to functions of neuronal systems and brain regions that are suspected of playing an important role in decision-making.

Detailed Description

The area of decision-making is a dynamically evolving, multifaceted area of active research that sits at the interfaces of many areas, among them psychology, neuroscience, economics, finance, political science, engineering, and mathematics. The range of decision-making tasks seen in the literature is extremely diverse, reflecting the interdisciplinary nature of the area and the diverse background of the researchers engaged in it. This entry attempts to summarize and categorize the major classes of decision-making tasks with respect to the formal, mathematically quantifiable properties of the tasks and the cognitive processes that may consequently be entailed. Broadly, decision-making tasks can be grouped into the following categories and subcategories:

- Decision-making under uncertainty
 - Sensory uncertainty
 - Outcome uncertainty
- Multidimensional decision-making
 - Target-distractor differentiation
 - Multisensory integration
- Preference-based decision-making

Decision-Making Under Uncertainty

Many decision-making tasks require the subjects to make choices among alternatives under conditions of uncertainty. Uncertainty can arise from noise related to sensory inputs, ignorance about stimulus or action outcomes, stochasticity or imprecise representation related to (relative) temporal onset of events, or some hybrid combinations of two or more of these factors. The

difficulty of the tasks can often be controlled parametrically via the level of uncertainty induced experimentally, and the tasks can therefore be used to probe fundamental limitations and properties of human and animal cognition, as well as characterize individual and group differences.

Sensory Uncertainty

Decision-making under sensory uncertainty, or *perceptual decision-making*, involves tasks in which the subject views a noisy stimulus and chooses a response consistent with the perceived response. One such widely used task is the random-dot coherent motion task (Newsome and Paré 1988), in which a field of flickering dots is displayed to the subject, a fraction (usually a minority) of which has simulated motion in a coherent direction, and the remainder either move in random directions (Newsome and Paré 1988) or have no discernible direction of motion (Shadlen and Newsome 2001). Based on the stimulus, the subject then chooses the appropriate response to indicate the perceived direction of coherent motion in the stimulus. This is usually done by eye movements in monkeys and either eye movements or key presses in humans. Typically, there are two possible directions of motion, out of which the subject must choose, making this a 2-alternative forced choice (2AFC) task; occasionally, it has been done with more than two alternatives or in a multiple-alternative forced choice (mAFC) format (Churchland et al. 2008). When the 2AFC version is done in conjunction with recordings of neurons that are sensitive to the direction of motion of the stimulus, the two possible directions of motion are chosen to be aligned with the preferred and anti-preferred directions of the neuron being recorded (Shadlen and Newsome 2001); in the mAFC version, one of the possible motion directions is aligned with the preferred direction of the neuron (Churchland et al. 2008).

There are two major variants of the random-dot coherent motion task, one in which the stimulus is present for a fixed duration (Newsome and Paré 1988) and one in which the stimulus is present until the subject makes a perceptual response (Roitman and Shadlen 2002). The latter, known

as the reaction time (RT) variant, is the behaviorally more interesting case, as it allows the subject to decide not only which stimulus was seen but how much sensory data to accumulate about the stimulus before responding. This has made this task a simple yet effective means for probing the speed-accuracy trade-off in perception (Gold and Shadlen 2002). Another property of the task that makes it ideal for examining the speed-accuracy trade-off is that it corrupts the sensory stimulus with a significant amount of noise that is identical and independent over time, making the informational value of the sensory stimulus constant over time (Bogacz et al. 2006). This property also gives the experimenter an accessible experimental parameter for controlling the information rate (signal-to-noise ratio) of the stimulus, through the coherence of the stimulus, or the percentage of coherently moving dots.

The mathematically optimal decision policy for choosing among two hypotheses based on independent, identically distributed data, where the observer can choose how much data to observe, is known as the sequential hypothesis ratio test (SPRT). It is the optimal policy for minimizing any cost function that is monotonically related to average reaction time and probability of error (Wald 1947; Wald and Wolfowitz 1948). It states that the observer should accumulate evidence, in the form of Bayesian posterior probability using Bayes rule or, equivalently, by summing up log odds ratios, until the total evidence exceeds a confidence bound that favors one or the other stimulus; then, at that point, the observer should terminate the observation process and choose the more probable alternative. The height of the decision boundary is determined by the relative importance of speed and accuracy in the objective function, with greater importance of speed relative to accuracy leading to lower decision boundaries, and vice versa for decreasing importance of speed relative to accuracy. In the limit when many data samples are observed before the decision is made, SPRT converges to the drift-diffusion process first studied in connection with statistical mechanics; it is essentially a bounded linear dynamical system with additive Wiener noise and absorbing boundaries (Laming

1968; Ratcliff and Rouder 1998; Bogacz et al. 2006). Many mathematical properties of the drift-diffusion process are well known, such as the average sample size before termination, and the probability of exceeding the correct boundary, for different problem parameters and task conditions. It therefore provides a convenient mathematical framework for analyzing SPRT and thus experimental behavior in different task settings.

A popular alternative to the 2AFC paradigm is the Go/NoGo (GNG) task, in which one stimulus requires a response (Go) and the other requires the response to be withheld (NoGo). One apparent advantage of the GNG paradigm is that it obviates the need for response selection (Donders 1969), thus helping to minimize any confounding influences of motor planning and execution when the experimental focus is on perceptual and cognitive processing. However, within-subject comparison of reaction time (RT) and error rates (ER) in 2AFC and Go/NoGo variants of the same perceptual decision-making task has found systematic biases between the two (Gomez et al. 2007). Specifically, the go stimulus in the Go/NoGo task elicits shorter RT and more false-alarm responses than in the 2AFC task, when paired with the same opposing stimulus in both paradigms, resulting in a Go bias. This raises the question of whether the two paradigms really probe the same underlying processes.

Existing mechanistic models of these choice tasks, mostly variants of the drift-diffusion model (DDM; Ratcliff and Smith 2004; Gomez et al. 2007) and the related leaky competing accumulator models (Usher and McClelland 2001; Bogacz et al. 2006), capture various aspects of behavioral performance, but do not clarify the provenance of the Go bias in GNG. Recently, it has been shown that the Go bias may arise as a strategic adjustment in response to the implicit asymmetry in the cost structure of the 2AFC and GNG tasks and need not imply any fundamental differences in the sensory and cognitive processes engaged in the two tasks. Specifically, the NoGo response requires waiting until the response deadline, while a Go response immediately terminates the current trial (Shenoy and Yu 2012). Using a Bayes-risk minimizing decision policy that minimizes not only error rate but also average decision

delay naturally exhibits the experimentally observed Go bias. The optimal decision policy is formally equivalent to a DDM with a *time-varying threshold* that initially rises after stimulus onset and collapses again just before the response deadline. The initial rise in the threshold is due to the diminishing temporal advantage of choosing the fast Go response compared to the fixed-delay NoGo response.

Outcome Uncertainty

This class of decision-making tasks is designed such that subjects have no uncertainty about the stimulus identity, but rather about the consequences of choosing one alternative over another. To induce such uncertainty, the subjects are not explicitly told about the reinforcement consequences of the different alternatives, but instead they have to learn them over time. The reinforcements are typically in the form of a reward, such as money for human subjects, juice for monkeys, or seeds for birds; but occasionally they can also be in the form of a penalty, such as money taken away for human subjects, a foot shock for rats, or air puff for rabbits. This class of task originated in the study of associative learning, which showed that subjects' asymptotic choice performance after substantial learning exhibited interesting features. For example, Herrnstein (Herrnstein 1961) found that pigeons, when faced with a choice between pecking two different buttons in a Skinner box, did not always choose the one with the higher reward rate, which is mathematically optimal, but rather alternated among the choices stochastically so as to "match" their underlying reward rates. Based on these results, Herrnstein formulated the "matching law" and the related "melioration theory" (Herrnstein 1970), which gave a procedural account of how matching-like behavior can arise from limited working memory. A more recent account, using Bayesian learning theory, shows that matching-like behavior is, at a finer timescale, the consequence of a maximizing choice strategy (always choosing the best options), coupled with a learning procedure that assumes the world to be nonstationary and thus

results in internal beliefs that fluctuate with empirical experiences, even those driven by noise in a truly stationary environment (Yu and Cohen 2009; Yu and Huang 2014).

In order to induce continual outcome uncertainty, many implementations of this task incorporate unpredictable, unannounced changes in the stimulus-outcome contingencies during the experimental session. A classical example of such a manipulation is reversal learning, in which the choice with the better outcome suddenly becomes the worse choice, while the previously bad choice now becomes the better choice. This type of tasks has been used to study, among other things, how perseverative tendencies might change as a function of experimental condition or manipulations of the neural circuitry in the brain. Such tasks are rich for theoretical modeling of the neural representation, computation, and utilization of different forms of uncertainty that arise during learning and decision-making (Yu and Dayan 2005; Nassar et al. 2010). For example, there is thought to be a differentiation of at least two kinds of uncertainties, “expected uncertainty,” dealing with known uncertainties and variabilities in the environment, and “unexpected uncertainty,” arising from dramatic, unexpected changes in the statistical contingencies in the environment. Experimentally, human subjects have been shown to be more ready to alter choice strategy under conditions of more frequent choice-outcome contingencies compared to when these changes are less frequent (Behrens et al. 2007); the upregulation of the neuromodulator norepinephrine has been shown to increase the rates for learning such changes (Devauges and Sara 1990); pupil diameter in human subjects, under the control of noradrenergic and cholinergic neuromodulatory systems, has also been shown to correspond to specific model-derived uncertainty signals (Nassar et al. 2012).

Multidimensional Decision-Making

There are two main types of multidimensional decision-making: (1) target-distractor differentiation, in which subjects must exclude the interfering influence of a distractor stimulus or attribute, in

order to focus on the target stimulus or attribute, and (2) multisensory integration, in which subjects must integrate multiple stimuli, often differing in sensory modalities, to reach a combined choice response.

Target-Distractor Differentiation

One classical task of this type is the Stroop task (Stroop 1935), in which subjects must ignore the meaning of a color word and report the physical color in which the text is written. Subjects consistently respond faster and more accurately when the meaning and physical attribute of the color word are congruent than when they are not. A related task is the Simon task, in which a stimulus present on one side (e.g., visual stimulus on the left side of the screen or auditory stimulus to the left ear) may instruct the subjects to respond with the other, less direct response (e.g., right button press), and again, performance is better when the two dimensions are congruent than when they are not (Simon 1967). Yet another similar task is the Eriksen task (Eriksen and Eriksen 1974), which requires the subject to identify a central stimulus (e.g., the letter “H” or “S”) when flanked on both sides by letters that are either congruent or incongruent with the central stimulus; again, subjects are significantly better in the congruent condition. These tasks have been used to discern how the brain identifies and filters out (or fails to do so) irrelevant distractors. Careful behavioral analysis of choice accuracy as a function of reaction time (Cho et al. 2002) has given clues as to the role of cognitive processes such as attentional control and stimulated theoretical modeling of the neural computations giving rise to specific features of the behavioral dynamics in such tasks (Yu et al. 2009).

A related but distinct class of tasks involves a prepotent “go” signal present on each trial and an occasional “stop” signal on a small fraction of trials, whereby the subject must execute the “go” response only on “go” trials and not on “stop” trials. In the stop-signal task (Logan and Cowan 1984), the “stop” signal appears, if at all, at an unpredictable time after the “go” stimulus, and the

greater the onset asynchrony, the more unlikely that the subject is able to withhold the “go” response. A related task is what has been called a “compelled-response task,” in which the subject is instructed to go *before* being shown the cue that indicates which of the two responses is correct (Salinas et al. 2010). These tasks have given rise to competing theoretical models that postulate either the existence (Logan and Cowan 1984) or absence (Shenoy and Yu 2011; Salinas and Stanford 2013) of a specific stopping process or pathway and, in the latter class, the precise capacity to stop depending on either a normative, sequential consideration of the pros and cons of responding (Shenoy and Yu 2011) or the efficiency of the perceptual process itself (Salinas and Stanford 2013). However, recent experimental results indicate systematic and rational changes in subjects’ stopping capacity as a function of the reward structure of the task (Leotti and Wager 2009), suggesting not only that the “go” response is context sensitive and strategically malleable but also that it takes into account perceptual uncertainty and decision-theoretical factors such as reward contingencies (Shenoy and Yu 2011).

Multisensory Integration

Instead of investigating how the brain selectively processes certain aspects of the environment and excludes others, simultaneously present stimuli have also been employed in experimental tasks to examine how the brain combines multiple sources of sensory information, in particular across sensory modalities. For instance, several studies in recent years have shown that human subjects combine differentially reliable sensory inputs from different modalities in a computationally optimal (Bayesian) way, such that greater weight is assigned to sensory inputs with less noise (and greater reliability) in the combined percept (Jacobs 1999; Ernst and Banks 2002; Battaglia et al. 2003; Dayan et al. 2000; Shams et al. 2005). This explains, for instance, why vision typically dominates over auditory modality in spatial localization in a phenomenon known as

“visual capture” – this follows directly from the Bayesian formulation, since vision has greater spatial acuity and reliability than audition (Battaglia et al. 2003). Conversely, when the localization task is in the temporal domain instead of spatial, where audition has greater temporal acuity and reliability, auditory stimuli can induce an illusory visual percept. For example, when a single visual flash is accompanied by several auditory beeps, the visual percept is that of several flashes (Shams et al. 2000). Again this phenomenon can be explained by a statistically optimal ideal observer model (Shams et al. 2005; Kording et al. 2007). Recent neurophysiological studies have also begun to elucidate the neural basis of multisensory integration [see, e.g., Driver and Noesselt (2008) for a review].

Preference-Based Decision-Making

One area of decision-making is devoted to the study of how humans make their choices based on their own internal preferences, such as in consumer decision-making, instead of based on sensory features or behavioral outcomes associated with the options. When choosing among options that differ along multiple attribute dimensions, humans consistently exhibit certain puzzling preference shifts, or even reversals, depending on the context. Three broad categories of contextual effects are studied in the psychology literature. In the *attraction effect*, given two similarly preferred options, A and B , the introduction of a third option Z that is similar to B , but also clearly less attractive than B , results in an increase in preference for B over A (Huber and Payne 1982; Heath and Chatterjee 1995). In the *compromise effect*, when $B > A$ in one attribute and $B < A$ in another attribute and Z has the same trade-off but is even more extreme than B , then B becomes the “compromise” option and becomes preferred relative to A (Simonson 1989). In the *similarity effect*, the introduction of a third option Z that is very similar to B in both attribute dimensions shifts the relative preference away from B to A (Tversky n.d.).

Traditionally, there have been two lines of explanations for such effects, the first attributing them to biases or suboptimalities in human decision-making (Kahneman and Tversky 1979; Kahneman et al. 1982) and the other suggesting that they are by-products of specific architectural or dynamical constraints on neural processing (Busemeyer and Townsend 1993; Usher and McClelland 2004; Trueblood 2012). A more recent, normative account (Shenoy and Yu 2013) uses a Bayesian model to demonstrate that these contextual effects can arise as rational consequences of three basic assumptions: (1) humans make preferential choices based on relative values anchored with respect to “fair market value,” which is inferred from both prior experience and the current set of available options; (2) different attributes are imperfect substitutes for one another, so that one unit of a scarce attribute is more valuable than one unit of an abundant one; and (3) uncertainty in beliefs about “market conditions” induces stochasticity in relative preference on repeated encounters with the same set of options. This model not only provides a principled explanation for *why* specific types of contextual modulation of preference choice exist, but a means to *infer* individual and group preferences in novel contexts given observed choices.

Decision-Making, Antisaccade Models of

Vassilis Cutsuridis

School of Computer Science, University of Lincoln, Lincoln, UK

Definition

The antisaccade task in its most typical form (the visually guided antisaccade; Fig. 1) is a reaction time task in which subjects are instructed to perform an immediate eye movement in the opposite direction to a peripheral stimulus, which is presented in their right or left visual field, while they are fixating on a central stimulus (Hallett 1978). Variations of the typical antisaccade (gap antisaccade and overlap antisaccade; Fig. 1) in the horizontal or vertical plane were designed over the years to investigate the effect of the fixation stimulus on the decision to move (Goldring and Fischer 1997; Forbes and Klein 1996; Fischer et al. 1997).

Decision-Making, Antisaccade Models of, Fig. 1 Basic design of the antisaccade task. Typically a participant starts each trial fixating on a stimulus. When a target stimulus appears, the participant must make an eye movement in the opposite direction (antisaccade) of the target stimulus. *Visually guided antisaccade*: the antisaccade is performed immediately after fixation stimulus (F) is extinguished and target stimulus (T) appears. *Gap antisaccade*: a gap period exists between disappearance of

Detailed Description

Basic Antisaccade Behavior

The antisaccade task was first developed to dissociate the stimulus location from the goal of the saccade. During a single trial of the antisaccade task two processes take place: (1) suppression of an erroneous prosaccade toward the peripheral stimulus and (2) generation of a volitional saccade to a position in the opposite direction (antisaccade) (Munoz and Everling 2004). In a single trial, a participant may express any of the following three oculomotor behaviors: (1) the subject makes an antisaccade (an eye movement in the opposite direction of the peripheral stimulus), or (2) the subject makes an erroneous prosaccade (an eye movement in the direction of the peripheral stimulus), or (3) the subject makes an erroneous prosaccade followed by a corrected antisaccade. An error is an eye movement toward the peripheral stimulus instead of the opposite direction. Antisaccade performance involves different metrics such as the mean and standard deviation of the saccade reaction time (SRT) of each eye movement as well as the error rate (Ettinger et al. 2003). Healthy participants typically fail to suppress erroneous prosaccades toward the target on about 20–25% of trials, before correctly saccading toward a location in the opposite direction (Fischer and Weber 1992; Everling and Fischer 1998; Smyrnis et al. 2002; Ettinger et al. 2003; Tatler and Hutton 2007). Unimodal skewed to the right distributions of antisaccades, erroneous prosaccades, and corrected antisaccades are observed. The mean and standard deviation of the antisaccade reaction time from a large cohort of 2006 healthy subjects is reported to be 270 ms and 56 ms, respectively (Evdokimidis et al. 2002). In the same group, the mean and standard deviation of the erroneous prosaccade reaction time is 208 ms and 46 ms, respectively, whereas the mean and standard

← **Decision-Making, Antisaccade Models of, Fig. 1** (continued) fixation stimulus and target stimulus appearance. *Overlap antisaccade*: fixation stimulus remains on during target stimulus presentation

deviation of the corrected antisaccade reaction time is 146 ms and 85 ms, respectively (Evdokimidis et al. 2002).

Antisaccade Oculomotor Circuit

The antisaccade oculomotor circuit consists of several cortical and subcortical areas including the frontal eye fields (FEF), supplementary eye fields (SEF), dorsolateral prefrontal cortex (DLPFC), anterior cingulate cortex (ACC), lateral intraparietal area (LIP) (parietal eye field (PEF) in the human), basal ganglia, thalamus, superior colliculus (SC), brainstem reticular formation, and cerebellum (Munoz and Everling 2004). Visual information is processed via the retinogeniculo-cortical pathway to primary visual cortex and from there to LIP/PEF and via the retinotectal pathway to the superficial layers of the SC (SCs). LIP is an area in the parietal cortex coding for space. LIP/PEF then projects to both the intermediate layers of the SC (SCi) and frontal cortical oculomotor areas including FEF, SEF, ACC, and DLPFC. FEF is critical for voluntary saccade execution. SEF is implicated in internally guided decision-making and sequencing of saccades. AAC plays a role in conflict resolution and error monitoring. DLPFC is critical in executive function, spatial working memory, and suppressing automated or reflexive responses. These frontal oculomotor areas project to SCi, an area important for decision-making, which then projects to the reticular formation of the brainstem to provide the necessary input to guide saccades.

Another pathway to SCi from the frontal oculomotor areas is through the basal ganglia structures via the direct, indirect, and hyperdirect pathways (Munoz and Everling 2004). Via the direct pathway, frontal areas project to the caudate nucleus (CD), which in turn inhibits the substantia nigra pars reticulata (SNr). SNr disinhibits the SCi and motor nuclei of thalamus, which project back to frontal cortex. Via the indirect pathway, CD projects to the external segment of the globus pallidus (GPe), which in turn projects to the subthalamic nucleus (STN). STN sends excitatory projections to SNr and GPe, which projects via GABAergic connections back to SNr. Via the hyperdirect pathway, cortical regions excite

STN, which in turn excite SNr. These complex sets of excitatory and inhibitory projections within the basal ganglia provide a rich set of control mechanisms to help guide voluntary behavior (Coe and Munoz 2017).

Primate Neurophysiology Overview

A number of brain areas in monkeys are involved in the antisaccade task, including the DLPFC (Funahashi et al. 1993), the ACC (Phillips et al. 2010), the LIP (Gottlieb and Goldberg 1999), the SEF (Schlag-Rey et al. 1997; Amador et al. 2004), the FEF (Everling and Munoz 2000), and the SC (Everling et al. 1999). Understanding how neurons in these brain areas participate in the suppression of automatic responses and the generation of antisaccades is crucial for explaining the antisaccade behavior.

Single neuron recordings in FEF and SC have revealed the existence of two distinct and reciprocally activated populations of neurons: the fixation cells and the saccade cells. Fixation cells are tonically active during visual fixation, and their activity ceases when a saccade is executed. On the other hand, saccade cells are silent during fixation but discharge when the animal is making a saccade. In SC, two distinct types of saccade neurons have been recorded: buildup and burst cells (Munoz and Wurtz 1995a, b). A network of inhibitory interneurons is thought to control the reciprocal activation of fixation and saccade neurons (Munoz and Istvan 1998). During fixation in the gap condition (gap prosaccade versus gap antisaccade), fixation activity is greater in the antisaccade trials than in the prosaccade trials in both FEF and SC. This pattern of enhanced fixation activity explains the so-called anti-effect (Munoz and Everling 2004): longer reaction times on antisaccade trials than on prosaccade trials. A few milliseconds into the gap period, there is a drop in activity of fixation neurons and a slow buildup of low-frequency activity of a subset of saccade neurons in both SC (Everling et al. 1999) and FEF (Everling and Munoz 2000). The appearance of the visual stimulus in the right visual field leads to phasic activation of visually responsive saccade neurons in FEF and SC on the contralateral (left) side of the brain, and to phasic inhibition of

saccade neurons on the ipsilateral (right) side of the brain. On the prosaccade trials, saccade neurons on the left side discharge a saccadic burst for the rightward prosaccade immediately after the visual phasic response. On antisaccade trials, the saccade neurons in the left FEF and SC are inhibited compared to saccade neurons in the right FEF and SC, which are active to drive the leftward antisaccade.

Recordings from neurons in PFC in rhesus monkeys trained to perform a delayed antisaccade task (Funahashi et al. 1993) revealed that most PFC neurons code the location of the visual stimulus in working memory, and this memory can be engaged to suppress and prescribe a response. Response-coding neurons in smaller percentages were also found, some of which increased their firing rate for the direction of the saccade (e.g., rightward saccade) irrespective of the stimulus location, and others coding for both stimulus location and saccade direction. Similarly, recordings in LIP (Gottlieb and Goldberg 1999) also revealed the majority of LIP neurons reliably coding for the encoded cue location, with only a very small minority encoding for the direction of the upcoming saccade.

Electrical microstimulation in dorsal AAC in monkeys performing alternating blocks of prosaccade and antisaccade trials (Philips et al. 2010) suggested a direct role of AAC in antisaccade performance. On antisaccade trials, microstimulation decreased SRTs for both ipsilateral- and contralateral-directed antisaccades. On the other hand on prosaccade trials, SRTs were increased for saccades contralateral to and decreased for saccades ipsilateral to the stimulated hemisphere.

Finally, recordings from SEF in monkeys (Amador et al. 2004; Schlag-Rey et al. 1997) showed that the vast majority of SEF movement neurons fired significantly more before antisaccades than before prosaccades. The level of their firing was predictive of the correct performance on antisaccades on individual trials.

Antisaccade Performance Across Lifespan

Antisaccade performance varies systematically with age (Munoz et al. 1998; Klein and Foerster

2001; Peltsch et al. 2011). Young children (5–8 years old) have slow SRTs, large intra-subject SRT variance, and the largest error rate in the anti-saccade task. Young adults (20–30 years of age) typically have the fastest SRTs, the lowest intra-subject variance in SRT, and the fewest direction errors. Elderly subjects (60–85 years of age) have slower SRTs than other subject groups. These results demonstrate very strong positive correlation of age and subject antisaccade performance, which may reflect different stages of normal development and degeneration in the nervous system. The dramatic improvement in antisaccade performance observed from the ages of 5 to 15 years is attributed to delayed maturation of the frontal lobes.

Antisaccade Performance in Disorders

Antisaccade performance has been investigated in many neurological and psychiatric disorders including attention deficit hyperactivity disorder (Munoz et al. 2003; Hakvoort Schwerdtfeger et al. 2013), fetal alcohol spectrum disorders (Green et al. 2007; Paolozza et al. 2013), Huntington disease (Peltsch et al. 2008), Parkinson's disease (Chan et al. 2005; Cameron et al. 2012; Cameron et al. 2010; Amador et al. 2006; Antoniadis et al. 2015), Alzheimer's disease (Peltsch et al. 2014; Kaufman et al. 2012), mild cognitive impairment (Peltsch et al. 2014; Heuer et al. 2013), amyotrophic lateral sclerosis (Witiuk et al. 2014), bipolar disease (Soncin et al. 2016), schizophrenia (Levy et al. 2004; Zanelli et al. 2005; Theleritis et al. 2014), obsessive-compulsive disorder (Lennertz et al. 2012; Jahanshahi and Rothwell 2017), Tourette syndrome (Jahanshahi and Rothwell 2017), multiple sclerosis (Clough et al. 2015), depression (Carvalho et al. 2014; Malsert et al. 2012), epilepsy (Lunn et al. 2016), ventrolateral prefrontal damage (Hodgson et al. 2007), and frontotemporal dementia (Burrell et al. 2012; Boxer et al. 2012).

In particular, patients with frontal lobe lesions (Guitton et al. 1985; Pierrot-Deseilligny et al. 2002) and patients suffering from schizophrenia (Fukushima et al. 1988) make more antisaccade errors and their antisaccade latencies are more variable within and across subjects (Fukushima

et al. 1988; Hutton et al. 1998; Karoumi et al. 1998; Brownstein et al. 2003). An increase in correct antisaccade mean latency in schizophrenia patients was recently reported (Damilou et al. 2016). Impaired antisaccade task performance has also been reported in patients with recent onset schizophrenia and first-episode schizophrenia (deWilde et al. 2008; Ettinger et al. 2004; Grootens et al. 2008; Hutton et al. 2002, 1998; Kirenskaya et al. 2013), chronic schizophrenia (Boudet et al. 2005; Curtis et al. 2001a; Fukushima et al. 1988; Behrwind et al. 2011), and remitted schizophrenia (Curtis et al. 2001b). Aberrant antisaccade performance has also been reported by first degree unaffected biological relatives of schizophrenia patients (Kang et al. 2011; Radant et al. 2010; Zanelli et al. 2009). The antisaccade performance deficit in schizophrenia patients is reported to be due to: (1) a deficit in top-down inhibition control of the erroneous response (Everling and Fischer 1998; Broerse et al. 2001; Brownstein et al. 2003; Curtis et al. 2001), (2) a deficit in response generation of the antisaccade (Everling and Fischer 1998; Broerse et al. 2001; Brownstein et al. 2003; Curtis et al. 2001), or (3) an emergent property of competing noisy decision accumulating processes (the erroneous prosaccade and the antisaccade) (Cutsuridis et al. 2014; Cutsuridis 2010).

Various psychopharmacological manipulations including administration of lorazepam (Green and King 1998; Green et al. 2000), risperidone (Burke and Reveley 2002; Hutton 2002), nicotine (Petrovsky et al. 2012; Rycroft et al. 2007; Depatie et al. 2002; Larrison-Faucher et al. 2004), amphetamine (Dursun et al. 1999), and modafinil (Rycroft et al. 2007) led to changes in the antisaccade performance of cohorts of patients. Risperidone has been observed to improve error rates in some schizophrenia patients (Burke and Reveley 2002; Hutton 2002). Nicotine administration in schizophrenia patients improves their antisaccade performance (Petrovsky et al. 2013; Depatie et al. 2002; Larrison-Faucher et al. 2004).

Antisaccade performance, on the other hand, of obsessive compulsive (OCD) patients has been variable and contradictory. Initial studies reported

increased error rates in OCD patients compared to healthy controls, but no difference in their latencies of antisaccades (Tien et al. 1992). Other studies reported higher antisaccade latencies in OCD patients compared to healthy controls, while their error rate did not differ significantly (Maruff et al. 1999; van der Wee et al. 2006). Another study observed no differences in error rates and latencies of antisaccades between OCD patients and healthy subjects (Kloft et al. 2011). An increase in error rates and in latency of corrected antisaccades was recently reported (Damilou et al. 2016). It is speculated that the OCD antisaccade performance is due to a deficit in erroneous response inhibition control in the oculomotor circuit (Chamberlain et al. 2005; Everling and Fischer 1998; Broerse et al. 2001; Brownstein et al. 2003; Curtis et al. 2001).

Types of Theoretical Models of Antisaccade Performance

Theoretical models of antisaccade performance fall under two categories:

- Accumulator models:** In these models, the process of decision-making often involves a *linear* gradual accumulation of information concerning the various potential responses starting at some baseline level S_0 , which represents the prior expectation, at a constant rate r until it reaches a threshold S_T , which represents the confidence level required before the commitment to a particular course of action. Once the decision signal crosses S_T , then a response toward the target is initiated. Response time (RT) is measured as the time from the onset of the decision process till when the decision signal crosses S_T . Often the rate of accumulation is assumed to vary randomly from trial to trial, with a mean μ and variance σ^2 (Reddi and Carpenter 2000). Changes in the baseline level of activity, the rate of accumulation, or the threshold often result in changes in response latency. Prior expectation and level of activation of intention influence the baseline levels of activation.

- **Neural accumulator models:** In these models, the accumulation process is represented by the firing rate of usually a population of neurons. Changes in the rate (slow or fast) of neural firing are usually *nonlinear*, often competing, and reflect the changes in the rate of accumulation in the linear accumulator.

Below I will review models of various degrees of antisaccade performance from both categories.

Accumulator Models

A notable modeling attempt of the antisaccade paradigm was Noorani's and Carpenter's (2013) three-unit model (see Fig. 2a). The model consisted of three LATER units racing to threshold: an ANTI unit, a PRO unit, and a STOP unit. An important model feature was that the ANTI unit was identical (μ and σ) to the PRO unit. In the model, the STOP unit prevented the PRO unit from reaching threshold, thus allowing the ANTI unit to reach a different threshold a little later. The authors hypothesized that the threshold level of the PRO unit was higher than the ANTI unit's threshold, reflecting the advice given by the experimenters to every subject to avoid errors. How often the STOP unit cancelled the PRO unit depended on its rate of accumulation (μ) and its variance (σ^2). The model's performance

was contrasted against the performance of five healthy subjects performing the antisaccade task. The model captured *most* of the response repertoire observed in the antisaccade task, namely the antisaccades and the erroneous prosaccades, their corresponding latency distributions, and the error response rate. Despite the model's successes, the model had several shortcomings. The model failed to produce "the erroneous prosaccade followed by the corrected antisaccade" behavior. Moreover, the model postulated the existence of a third inhibitory signal (the STOP signal), which occasionally stopped the erroneous prosaccade response and indirectly allowed just the anti-saccade response to be expressed. Recent experimental evidence has challenged the existence of such a third signal (Everling and Johnston 2013).

To address some of these shortcomings, Noorani and Carpenter (2014) extended their previous model (Noorani and Carpenter 2013) by including a RESTART mechanism (see Fig. 2b). In this case, when the PRO unit reached the threshold first, it restarted the ANTI unit allowing it to reach the threshold and generate the anti-saccade response. Their new model successfully reproduced the "erroneous prosaccade followed by the corrected antisaccade" behavior, but failed now to reproduce the *just* erroneous prosaccades. This shortcoming was inherent in their model.

Decision-Making, Antisaccade Models of, Fig. 2 (a) Three-unit antisaccade model. (b) Three-unit antisaccade model with RESTART mechanism

The authors postulated that if the STOP signal did not prevent the erroneous prosaccade response, then the PRO unit will *always* restart the ANTI unit (Noorani and Carpenter 2014). This meant the erroneous prosaccades followed by corrected antisaccades will always be produced. If the STOP unit did prevent the PRO unit, then the ANTI unit would not restart (the corrected antisaccade will not be produced), and an antisaccade response would be generated (Noorani and Carpenter 2014). In either scenario, *just* an erroneous prosaccade response cannot be generated. The authors claimed in their studies participants never made any *just* erroneous prosaccades (private communication of the author with Roger Carpenter). However, psychophysical studies of a large group of 2006 participants performing the antisaccade task (Evdokimidis et al. 2002) reported that subjects do make the *just* erroneous prosaccades, but their response frequency is low. Another limitation of their new model was their consideration that the simulated latency of the corrected antisaccade is the result of the linear sum of latencies of the erroneous prosaccade and the antisaccade minus the latency of the STOP activity. This shortcoming was inherent in the model, because its units are considered linear encoders of the input information.

The three-unit antisaccade model was recently applied to a large sample of Huntington’s disease (HD) patients against healthy controls in an effort to quantitatively predict HD before symptom onset (Wiecki et al. 2016). Experimental RT distributions and error rates of pre-manifest individuals carrying the HD mutation (pre-HD), early symptomatic, and healthy controls performing the antisaccade conflict task were fit using the three-unit antisaccade model. Further machine learning analysis based on fitted model parameters revealed a key executive control parameter was predictive of HD prior to symptom onset, whereas response inhibition processes are impaired only after the motor symptoms are observed.

Extensions of the three-unit antisaccade model were very recently introduced by Aponte et al. (2017) in the form of three probabilistic models, PROSA, SERIA, and SERIA_{lr}. SERIA_{lr} (see Fig. 3) predicted that two decision processes (one early race between a prepotent response toward a target and an endogenously generated signal to cancel this action, and a secondary late race between two units encoding two cue-action mappings) are necessary to properly model the antisaccade task. The two decision processes in SERIA_{lr} were considered to be the sources of early errors, fast erroneous prosaccades in

Decision-Making, Antisaccade Models of, Fig. 3 SERIA_{lr} model. The presentation of a visual cue (target) triggers the race of four independent units.. The Stop unit can stop an early response. The late decision process is triggered by the competition between two further units

D

Decision-Making, Antisaccade Models of, Fig. 4 Three module neural accumulator model of antisaccade performance of healthy controls (Cutsuridis et al. 2007a, b). A reactive input (LIP population output) and a planned input (FEF population output) activate the superior colliculus module. Both inputs have a linearly rising phase, whose slope varies from a normal distribution, a

plateau phase, and an offset phase. Lateral inhibitory interactions between cells mediate the inhibitory effects of inhibitory interneurons in the superior colliculus. P: cortical pyramidal cell; I: cortical inhibitory interneuron; Black node: SC fixation cell; Dark gray node: SC buildup cell; Light gray node: SC burst cell

antisaccade trials, and late errors, late actions incongruent with the cue presented. Bayesian model comparison showed that the SERIA_{lr} model explains the data better than other competing models that did not incorporate a late decision process. Early decision processes were predicted to be insensitive to cue presented in every trial. Changes in reaction time and error rate due to probability of trial type were best explained by faster or slower inhibition in the model.

Neural Accumulator Models

Rate-Based Models

The first ever attempt to simulate the antisaccade task and uncover its neural mechanisms was made by Cutsuridis et al. (2007a) when they introduced a neural nonlinear accumulator model with competition via lateral inhibition between its components. The model was a 1D layer neuronal arrangement of the intermediate layer of SC with three different types of cells, namely the fixation,

buildup, and burst neurons (Trappenberg et al. 2001) (see Fig. 4). In the model, the fixation cells were activated by the fixation stimulus, and the buildup and burst cells by two inputs, a reactive input that represented the erroneous prosaccade motor plan and originated from the lateral intraparietal (LIP) area (Gottlieb and Goldberg 1999) and a planned input which represented the antisaccade motor plan and originated from FEF (Everling and Munoz 2000). The inputs were linear ramping processes till a maximum value after which they were either abruptly brought or smoothly decayed to zero. The slopes values of these linearly ramping processes took values from Gaussian distributions with different means and standard deviations for each input. Both inputs were integrated by spatially distant buildup and burst cells, which competed one another via lateral inhibition (Munoz and Istvan 1998). Each simulation trial started with the model fixation cells firing maximally for as much time as the subjects were fixating to the

central stimulus and buildup and burst cells being silent. As soon as the peripheral stimulus appeared and the subjects had to make an antisaccade, then the model fixation activity started to decay to zero and the buildup cell activity started to rise. In the model, the buildup cells had the role of accumulator cells that integrated evidence till some user pre-set threshold. Once the threshold was crossed, then the cue was given to the model burst cells to fire maximally, but for a short period of time (phasic activation). In the model, the burst activity represented the final motor command given to the eyes to move. Occasionally, in some simulated trials both erroneous prosaccade and antisaccade buildup cells crossed the threshold, which then cued their corresponding burst cells to fire. Behaviorally that meant that the virtual subject made an erroneous prosaccade first and corrected with an antisaccade. The model was able to produce all three oculomotor behaviors of the antisaccade task, namely the erroneous prosaccade, the antisaccade, and the corrected antisaccade. The model was also able to simulate accurately the antisaccade performance (latency distributions of the erroneous prosaccades and antisaccades as well as the error rates) of 10 virtual groups of participants with only five free parameters. The model predicted that competition via lateral inhibition and

not a third inhibitory signal accounts for the antisaccade performance of a large cohort of healthy participants. Despite its successes the model suffered from shortcomings. The simulated discharged rates of the fixation and buildup cells were unrealistically high (roughly 600 Hz) (Munoz and Wurz 1993, 1995a, b). For lower discharged rates the model can still accurately simulate the behavioral and neurophysiological properties of the antisaccade task, but for different parameter values (unpublished observations). Furthermore, the model failed to uncover the ionic and synaptic mechanisms that may produce the range of values of input slopes needed to produce the latency distributions of the erroneous prosaccades and antisaccades.

Recently, Cutsuridis extended his neural non-linear accumulator with competition model of antisaccade performance (Cutsuridis et al. 2007a) into the disorder domains of schizophrenia and obsessive-compulsive disorder (OCD) (Cutsuridis et al. 2014; Cutsuridis 2017a, b). In the new model (see Fig. 5), variations in the integration constants of buildup cell activities in the model SC and not in the slopes of the ramping phases of the cortical inputs produced the error rates and latency distributions of the erroneous prosaccades, antisaccades, and corrected antisaccades of healthy controls

Decision-Making, Antisaccade Models of,
Fig. 5 Neural accumulator model of antisaccade performance of schizophrenia and OCD patients (Cutsuridis et al. 2014; Cutsuridis 2017b). Two inputs activate opposite sides of the superior colliculus: a reactive input originating from LIP and a planned input originating from FEF. Each

node in SC excites itself and inhibits its neighbors (on-center, off-surround connectivity). Lateral inhibitory interactions between cells mediate the inhibitory effects of inhibitory interneurons in the superior colliculus. Gray node: SC buildup cell

(Ettinger et al. 2003), schizophrenia, and OCD (Damilou et al. 2016) suffering subjects. The model showed that the poor antisaccade performance in schizophrenia is due to a more noisy accumulation of information, but the schizophrenia patients are as confident (threshold level is unchanged) as their healthy counterparts (Cutsuridis et al. 2014). In contrast, in OCD, the accumulation of information is also noisy, but the OCD subjects are less confident (threshold level is changed) than the healthy participants (Cutsuridis 2017b). In both disorders, the model predicted the antisaccade performance is *not* due to a deficit in the top-down inhibitory control of the erroneous response as many speculated, but instead it is due to a local inhibitory mechanism in the form of a competitive race to a threshold between the buildup cell representations of the erroneous prosaccade and antisaccade in SC. In favor of this competitive race to a threshold between competing prosaccade and antisaccade signals is the Massen (2004) study, which selectively manipulated the exogenous and endogenous processes in the antisaccade task (e.g., slowing down or speeding up one of these or both processes) and observed the effects of this manipulation on error rate. Massen (2004) observed that if a manipulation slowed the generation of antisaccades, while having no effect on prosaccade generation, then the error rate was increased. If, however, manipulation influenced both pro- and antisaccade generation to the same degree, then the error rate remained unchanged. Massen (2004) argued that antisaccade performance is explained in terms of a competition between two parallel programs for saccade execution: if the volitional antisaccade is programmed fast enough (e.g., reaches some threshold for activation), then it will win the competition, and the reflexive prosaccade will be cancelled. Alternatively, if the prosaccade is programmed fast enough or the computation for the antisaccade is too slow, an erroneous prosaccade will be made first followed by the correct antisaccade. This account is in line with Cutsuridis et al.'s (2007a, 2014, 2017b) computational studies favored the concept of an active inhibitory mechanism in the form of competition between competing decision signals as being critical to antisaccade performance.

Spiking Neuron Models

To uncover the ionic and synaptic mechanisms that produced the range of values of accumulation rates needed to produce the latency distributions of the erroneous prosaccades and antisaccades in Cutsuridis et al.'s (2007a) model, the same group (Cutsuridis et al. 2007b) introduced a multi-modular neural network model consisting of two cortical modules (FEF and LIP) that drove the SC module to decide the winning motor command to move the eyes (Fig. 4). Each cortical module was a network of Hodgkin-Huxley type excitatory and inhibitory neurons connected together. The SC module was the same as in Cutsuridis et al.'s (2007a) study. No connectivity was assumed between the cortical modules, although it has been experimentally observed (Schall 1997). Symmetric and asymmetric connection types were tried. Background noise and synaptic noise were also included in the cortical model neurons and in their connections to simulate homogeneous and heterogeneous neuronal firings. The population activity from each cortical network was extracted and a line was fitted to its ramping activity to estimate its slope. Variations in all model ionic and synaptic conductances were attempted to uncover which current(s) and what range of their conductance values reproduced the full range of slope values of the planned and reactive inputs to the SC model needed to reproduce the latency distributions and error rates of the virtual groups of participants in the Cutsuridis et al.'s (2007a) study. The model predicted that only conductance variations of the persistent Na^+ , NMDA and AMPA currents could produce the necessary slope variability in the cortical decision signals to reproduce the latency distributions and response probabilities of the virtual subjects.

Recently, a two-module spiking with competition network model of antisaccade performance was advanced by Lo and Wang (2016). The model consisting of sensorimotor remapping and action selection modules, the latter endowed by a "Stop" process through tonic inhibition, both under the modulation of rule-dependent control revealed the circuit mechanisms for the experimentally observed distributions of erroneous responses in the antisaccade task. In the model, fast errors

resulted from failing to inhibit the quick automatic responses and therefore exhibited very short response times. Slow errors, on the other hand, were due to an incorrect decision in the remapping process and exhibited long response times comparable to those of correct antisaccade responses.

Decision-Making, Bias

Marijn van Wingerden and Tobias Kalenscher
Department of Comparative Psychology, Institute
of Experimental Psychology, Heinrich-Heine
University Düsseldorf, Düsseldorf, Germany

Definition

Biases in decision making are identified as patterns of choice behavior that violate normative theory of choice allocation.

Detailed Description

According to the axioms frequently used in economic theory, a *rational decision maker* is an agent who makes consistent choices over time, and therefore exhibits stable *preferences* (Samuelson 1938; Friedman and Savage 1948, 1952). Importantly, the rationality assumption does not prescribe that the decision maker should always optimize her objective outcome, e.g., her monetary payoff, but it does prescribe that an individual should behave consistently, given the assumption of stable preferences. This rationality assumption has been applied to both human and animal behavior (Kacelnik 2006). However, both in the human and animal literature, numerous examples of violations of economic rationality, i.e., biases in decision making, can be found (Kalenscher and Van Wingerden 2011).

Present Bias and Time-Inconsistent Preferences

A ubiquitous finding in decision making studies is that decision makers prefer immediate or briefly

delayed outcomes over longer delayed outcomes (e.g., Ainslie 1974; Green et al. 1994; see Kalenscher and Pennartz 2008 for a review), even if the delayed outcomes clearly constitute the better long-term choice (e.g., saving for a pension plan vs. drinking away your money today). This myopic choice behavior is usually termed ‘impulsivity’. Impulsive, shortsighted intertemporal decision making violates several assumptions made in rational choice theories, such as Discounted Utility Theory (DUT). DUT is a normative account of decision-making over time, which predicts a rational decision maker’s preference for immediate over delayed reward (see ► “Choice Behavior”). DUT states that agents should maximize discounted utility when making intertemporal decision, where discounted utility reflects the reduced current value incurred by options that are deferred into the future. For example, when choosing between a smaller, sooner (SS) or a larger, later (LL) outcome, an agent’s discount function combined with the duration of the delays could lead a decision maker to prefer SS over LL or vice versa, depending on the delays and magnitudes involved. Importantly, for a rational decision maker, such preferences are assumed to be stable. Specifically, one of the predictions of DUT is that decision makers discount future rewards at a constant rate. This means that, if a decision maker reveals a preference for, say, an SS outcome delivered after delay t_1 over an LL outcome delivered after delay t_2 , with $t_1 < t_2$, she should still prefer the SS outcome if both outcomes are deferred into the future by the same time interval Δt , because both outcomes would be discounted at the same rate. However, in contrast to the assumption of stable intertemporal preferences, in practice, most human as well as animal decision makers exhibit *preference reversals*, typically changing their choice behavior from preferring the SS to preferring the LL outcome when a common front-end delay (Δt) is added (Rachlin and Green 1972; Ainslie 1974; Bateson and Kacelnik 1996; Isles et al. 2003; Kalenscher et al. 2005; Kalenscher and Pennartz 2008; Louie and Glimcher 2010; Kalenscher and van Wingerden 2011). Assuming that the overt choice behavior reflects an internal ranking of discounted

utility, this implies that the time-discounted utility attached to the SS option has sunk below that of the LL, invalidating constant discounting.

DUT is agnostic about whether a given SS should be preferred over an LL alternative. In the context of animal foraging, however, optimal foraging theory (Charnov 1976; Stephens and Krebs 1986) prescribes *long-term rate maximization* to increase Darwinian fitness (see ► “Choice Behavior”). In self-control paradigms, paradoxically, animals typically fail to optimize their long-term rates. Imagine an SS option yields reward G_1 after some time t_1 while an LL option yields G_2 after t_2 . The choice is presented to the animals after some inter-trial interval τ . A long-term rate maximizing decision rule (Stephens and Krebs 1986) would predict that animals should always choose the LL alternative G_2 if its long-term rate exceeds that of the SS option G_1 . Animals typically exhibit present-bias, a failure to maximize long-term rates, by choosing the SS option even when a post-feeding delay (p) is added to it, making the trial durations equivalent (Mazur and Logue 1978; Green et al. 1981).

$$\frac{G_2}{\tau + t_2} > \frac{G_1}{\tau + t_1 + p} \quad (1)$$

How can such time-inconsistent behavior be explained? Two-system models of decision making posit that the utility premium put on immediate over delayed outcomes can be traced to different (competing) neural systems that process immediate vs. delayed outcomes. McClure et al. (2004, 2007) and others have shown that ‘limbic’ regions such as the ventromedial prefrontal cortex and ventral striatum (Hariri et al. 2006) are preferentially activated by immediate outcomes, while other prefrontal structures such as lateral prefrontal cortex are engaged by both immediate and delayed outcomes. The inverse of impulsivity, self-control, can be invoked to combat present-bias in decision making. Hare et al. (2009, 2011) have shown that activity in dorsolateral prefrontal cortex is associated with self control, and that this activity can modulate value signals in ventromedial prefrontal cortex, downregulating the value of

liked, but unwanted outcomes when self control succeeds.

Certainty Effect in Decision Making

In decision making under risk, the normatively flavored Expected Utility Theory framework (EUT, see Choice Behavior) posits that monetary outcomes are nonlinearly transformed to subjective value or *utility*. This transformation can explain the commonly found risk-aversion when choosing between a certain and a probabilistic outcome. EUT assumes that, while gains are non-linearly transformed, probabilities are not, so that each outcome’s expected utility is the linearly weighted sum of the probability-weighted utilities of the possible outcomes. However, behavioral data show that decision makers over-value certain outcomes. The Allais paradox supports this notion by showing that adding a probabilistic outcome to two gambles in a choice set, so that one of the options now becomes certain instead of probabilistic, induces decision makers to reverse their preferences (Allais 1953; Kahneman and Tversky 1979; Hsu et al. 2009). So, suppose that the choices are a large gain G_1 with a low probability P_1 or a small gain G_2 with high probability P_2 , and the subject prefers the first, riskier option. According to the independence axiom of EUT, the preference should be the same when the same probabilistic outcome is added to both options. So, if a gain G_2 with probability $(1 - P_2)$ is now added to *both* choices, both expected outcomes increase by the same amount, but the second one becomes certain, i.e., G_2 with a probability of 1, and in this case decision makers typically prefer the second option, reversing their original preference. In other words, decision makers have a strong preference for outcomes that are certain over outcomes that are probabilistic, even if the expected utility ranking is maintained. A recent brain imaging study (Hsu et al. 2009) building on *prospect theory* (Kahneman and Tversky 1979; Tversky and Kahneman 1992) indicates that neural activity in the striatum when evaluating probabilistic outcomes is better explained by a non-linear

(reverse-S shaped) function than a strictly linear function. In animals studies, results that resemble Allais-like certainty effects are observed in rats (MacDonald et al. 1991) and honeybees (Shafir et al. 2008).

Sign/Reflection Effects in Decision Making

Economic theory usually assumes a monotonically increasing utility function linking objective quantities of a good to a subjective valuation as the basis for preference judgments (Samuelson 1937, 1938; von Neumann and Morgenstern 1944). When outcomes are not certain, EUT prescribes that the expected utility of a choice can be calculated simply by weighing the utilities of the possible outcomes of a decision by their probabilities and summing across these outcomes (see ► “Choice Behavior”). According to EUT, a decision maker should base her choice on the final state of wealth, taking into account all (discounted) utilities of all outcomes, and it should not matter whether changes in good quantities are accounted as gains or losses. However, humans seem to treat gains differently to losses. Because of the concave, decelerating nature of the utility function, humans tend to be risk-averse when choosing between gambles with gains. However, when the gambles are presented as potential losses rather than gains, risk attitudes often change from risk-averse to risk-seeking (Kahneman and Tversky 1979, 1984). This is called the *reflection effect*, the finding that risk attitudes change when the prospects flip around 0.

Further indications that losses are treated differently from gains come from research on *loss aversion* (Kahneman and Tversky 1984; Tversky and Kahneman 1992). The idea that losses loom larger than gains is illustrated by the fact that most participants reject a 50/50 gamble on a coin toss or fair die. In fact, the gains need to be about twice as big to offset the potential loss. In the brain, several areas including the VStr and ventromedial prefrontal cortex (vmPFC) show a pattern of ‘neural’ loss aversion – that is, the slope of BOLD deactivations to losses is steeper than activations to

gains, when mixed gambles of potential losses and gains are evaluated (Tom et al. 2007). In animals, loss aversion is also observed (Chen et al. 2006; but see Silberberg et al. 2008).

Framing Effect in Decision Making

The differential treatment of losses and gains is even more strikingly evident in the *framing effect*. Kahneman and Tversky (1984) showed that when a decision has to be made between a certain and a probabilistic outcome on human lives saved (gain frame) versus lost (loss frame), with the exact same numerical outcomes, the gain frame induces risk aversion whereas the loss frame induces risk seeking choice behavior in participants. This shows that the wording used to present a decision problem is sufficient to bias a subject between treating identical outcomes as gains or losses, and affecting risk attitude accordingly. There is some evidence that decisions in the direction of the framing effect, as opposed to those decisions in opposition to the choice biases, elicit more activity in the amygdala (De Martino et al. 2006; but see Talmi et al. 2010), and that resilience against the framing bias is associated with activity in OFC. In animals, starlings show behavior in line with a framing effect. When the baseline expectation of a food outcome is either low (gain frame) or high (loss frame), the birds are more prone towards risk-averse behavior (selecting the fixed outcome) or risk-seeking behavior (selecting the probabilistic outcome), respectively (Marsh and Kacelnik 2002).

Non-stationary Preferences: Intransitivity

A rational decision maker should exhibit stable preferences. Formally, if a decision maker prefers A over B and B over C, she should also prefer A over C (transitivity of preferences). However, human subjects often show *context-dependent* or *intransitive choices* (Tversky 1969; Kalenscher and Pennartz 2010; Kalenscher et al. 2010). Intransitive preferences seem to occur readily

when choice options differ on several value-related attributes, such as probability and reward magnitude, and could stem from an attribute-wise comparison instead of an alternative-wise integration of choice attributes. For instance, consistent with the *additive difference model* put forward by Tversky (1969), Kalenscher et al. (2010) showed that participants choosing between two gambles tend to weigh differences in probabilities and reward magnitudes differentially. So, a large difference in probabilities (with a moderate difference in reward magnitude) resulted in a strong weighting of this attribute, and correspondingly risk-averse choices, whereas a large difference in reward magnitude (with a moderate difference in probability) resulted in a strong weighting of magnitude, together with risk-seeking choices. This context-dependent shift from risk-aversion to risk-seeking, depending on the difference in the gambles' attributes, rendered the potential for circular, intransitive preference structures. The neural data by Kalenscher et al. support separate tracking of the context-dependent weight of outcome probabilities (posterior cingulate cortex) and magnitudes (posterior insula).

Sunk Cost Effect in Decision Making

The sunk cost effect is the tendency to persist in an endeavor once an investment of effort, time, or money has been made (Thaler 1980). A famous example entails the continuation of the *Concorde* supersonic airplane project, even when profitability analyses indicated that the project would never make money (Arkes and Ayton 1999). Besides policy makers, participants in the lab also exhibit the sunk cost effect. Navarro and Fantino (2005) and others have shown that human participants persist in a choice option searching for payout beyond the moment when switching, abandoning or resetting would be optimal (Kogut 1990). In animals, sunk costs have been studied in pigeons. Like humans, pigeons generally persisted longer on a probabilistic choice than prescribed by optimal choice, and this persistence was modulated by the size of the sunk costs (Navarro and Fantino 2005; Pattison et al. 2012).

Prosocial Biases in Decision Making

One of the tenets of microeconomic theory is that decisions should be made from a purely self-interested perspective, and that other people's outcomes should be disregarded. Obviously, this notion does not conform to reality. Human decision makers experience consistent prosocial biases that become manifest in costly helping behavior, e.g., when an agent reduces her own outcome in favor of another's. The most straightforward example of this is the Dictator Game (DG; Fehr and Fischbacher 2003; Engel 2011), where a participant can split a sum of money between herself and a powerless partner. The partner has to accept, and cannot retaliate. From a game theoretical perspective, the dictator should keep all the money for herself. This is not the case, people across all cultures and socio-economic groups consistently give sums larger than 0, even in anonymous, one-shot games where reputation building or other strategic motives can be ruled out (Fehr and Fischbacher 2003; Engel 2011). This suggests that decision makers are presumably not the selfish, own-payoff maximizers postulated by economic theory, but do take the well-being of others into consideration.

Definition

Models of decision making attempt to describe, using stochastic differential equations which represent either neural activity or more abstract psychological variables, the dynamical process that produces a commitment to a single action/outcome as a result of incoming evidence that can be ambiguous as to the action it supports.

Detailed Description

Background

Decision making can be separated into four processes (Doya 2008):

1. Acquisition of sensory information to determine the **state** of the environment and the organism within it.
2. Evaluation of potential actions (options) in terms of the cost and benefit to the organism given its belief about the current state.
3. Selection of an **action** based on, ideally, an optimal trade-off between the costs and benefits.
4. Use of the outcome of the action to update the costs and benefits associated with it.

Models of the dynamics of decision making have focused on perceptual decisions with only two possible responses available. The term two-alternative forced choice (TAFC) applies to such tasks when two stimuli are provided, but the term is now generally used for any binary choice discrimination task.

In a perceptual decision, the response, or action, is directly determined by the current percept. Thus, the decision in these tasks is essentially one of perceptual categorization, namely, process (1) above, though the same models can be used for action selection given ambiguous information of the current state (process 3).

Evaluation of the possible responses in terms of their value or the resulting state's utility (process 2) (Sugrue et al. 2005) given both uncertainty in the current state, and uncertainty in the outcomes of an action given the state, is the subject of expected utility theory and prospect theory.

The necessary learning and updating of the values of different actions given the actual outcomes they produce (process 4) are the subject of instrumental conditioning and reinforcement learning, for example, via temporal difference learning (Seymour et al. 2004) and actor-critic models (Joel et al. 2002).

This entry is primarily concerned with the dynamics of the production of either a single percept given unreliable sensory evidence (1) or a single action given uncertainty in the outcomes (3).

General Features of Discrimination Tasks or TAFC Tasks

In a TAFC task, a single decision variable can be defined representing the likelihood ratio – the probability that evidence to date favors one alternative over the other. While TAFC tasks (Fig. 1) have provided the dominant paradigm for analysis of choice behavior, the restriction to only two choices is lifted in many of the more recent models of decision making based on multiple variables, allowing for the fitting of a wider range of data sets.

The tasks can be based on either a free-response paradigm, in which a subject responds after as much or little time as she wants, or an

Decision-Making, Models, Fig. 1 Scheme of the two-alternative forced-choice (TAFC) task. Two streams of sensory input, each containing stimulus information, or a signal ($S1$ and $S2$) combined with noise ($\sigma_1 \eta_1(t)$ and $\sigma_2 \eta_2(t)$), are compared in a decision-making circuit. The circuit must produce one of two responses (A or B) indicating which of the two signals is stronger. The optimal method for achieving this discrimination is via the sequential probability ratio test (SPRT) which requires the decision-making circuit to integrate inputs over time

interrogation (forced response) paradigm, in which the stimulus duration is limited and the subject must make a response within a given time interval. The free-response paradigm is perhaps more powerful, since each trial produces two types of information: accuracy (correct or incorrect) and response time. However, by variation of the time allowed when responses are forced, both paradigms are valuable for constraining models, since they can provide a distribution of response times for both correct and incorrect trials, as well as the proportion of trials that are correct or incorrect with a given stimulus. These behavioral data can be modified by task difficulty, task instructions (such as “respond rapidly” versus “respond accurately”), or reward schedules and intertrial intervals.

Most models of the dynamics of decision making focus on tasks where the time from stimulus onset to response is no more than one to two seconds, a timescale over which neural spiking can be maintained. Choices requiring much more time than this are likely to depend upon multiple memory stores, neural circuits, and strategies, which become difficult to identify, extract, and model in a dynamical systems framework (a state-based framework is more appropriate).

In the standard setup of the models, two parallel streams of noisy sensory input are available,

with each stream supplying evidence in support of one of the two allowed actions (see Fig. 1). The sensory inputs can be of either discrete or continuous quantities and can arrive discretely or continuously in time. The majority of models focus on continuous update in continuous time so they can be formulated as stochastic differential equations (Gillespie 1992; Lawler 2006). The sensory evidence, which is momentary, produces a decision variable, which indicates the likelihood of choosing one of the two alternatives given current evidence and all prior evidence. The primary difference between models is in how sensory evidence determines the decision variable. While most models incorporate a form of temporal integration of evidence (Cain and Shea-Brown 2012) and include a negative interaction between the two sources of evidence, differences arise in the stability of initial states which determines whether integration is perfect and in the nature of the interaction: feedforward between the inputs, feedforward between outputs, or feedback from outputs to decision variables (Bogacz et al. 2006). Models can also differ in their choice of *decision threshold* – the value of the decision variable at which a response is produced – in the free-response paradigm (Simen et al. 2009; Deneve 2012; Drugowitsch et al. 2012) and in particular whether this parameter or other model parameters, such as input gain, which also affect the response time distribution, are static or dynamical across a trial (Shea-Brown et al. 2008; Thura et al. 2012).

As the time available for acquisition of sensory information increases, so does the accuracy of responses in a perceptual discrimination task. Accuracy is measured as probability of choosing the response leading to more reward, which is equivalent to obtaining a veridical percept in these tasks. All of the models to be discussed below can produce such a speed-accuracy trade-off by parameter adjustment. If parameters are adjusted so as to increase the mean response time, then accuracy increases. Such a trade-off is observed in behavioral tasks under two regimes: one, when either instructions or the schedule of reward and punishment encourages participants to respond as quickly as possible while being less concerned about making errors or two, when

subjects respond as accurately as possible while being less concerned about the time it takes to decide. The simplest way to effect such a trade-off is to adjust the intertrial interval, which if long compared to the decision time means that accuracy of responses impacts reward rate much more so than the time for the decision itself. Models can replicate such behavior when optimal performance is based on the maximal reward rate. Typical parameter adjustments to increase accuracy while slowing responses would be a multiplicative scaling down of inputs (and the concurrent input noise) or a scaling up of the range across which the decision variable can vary by raising a decision threshold (Figs. 2 and 3) (Ratcliff 2002; Simen et al. 2009; Balci et al. 2011). A similar effect can be achieved in alternative, attractor-based models through the level of a global applied current, which affects the stability of the initial “undecided” state (Figs. 6–9) (Miller and Katz 2013).

From a neuroscience perspective, the decision variable is typically interpreted as either the mean firing rate of a group of neurons or a linear combination of rates of many neurons (Beck et al. 2008), the difference between two groups being the simplest such combination. There has been remarkable progress in matching the observed firing patterns of neurons (Newsome et al. 1989; Shadlen and Newsome 2001; Huk and Shadlen 2005) with the dynamics of a decision variable in more mathematical models of decision making (Glimcher 2001, 2003; Gold and Shadlen 2001, 2007; Smith and Ratcliff 2004; Ratcliff et al.

2007). This has led to the introduction of biophysically based models of neural circuits (Wang 2008), which have accounted for much of the concordance between simple mathematical models, neural activity, and behavior.

Optimal Decision Making

An optimal decision-making strategy either maximizes expected reward over a given time or minimizes risk. In TAFC perceptual tasks, a response is either correct or an error. In the interrogation paradigm, with fixed time per decision, the optimal strategy is the one leading to greatest accuracy, that is, the lowest expected error rate. In the free-response paradigm, the optimal strategy either delivers the greatest accuracy for a given mean response time or produces the fastest mean response time for a given accuracy. In these tasks, the sequential probability ratio test (SPRT), introduced by Wald and Wolfowitz (Wald 1947; Wald and Wolfowitz 1948), and, in its continuous form, the drift-diffusion model (DDM) (Ratcliff and Smith 2004; Ratcliff and McKoon; 2008) lead to optimal choice behavior by any of these measures of optimality (see (Bogacz et al. 2006) for a thorough review).

Using SPRT in the interrogation paradigm, one simply accumulates over time the log-likelihood ratio of the probabilities of each alternative given the stream of evidence, where the observed sensory input per unit time has a certain probability given alternative A and another probability given alternative B. Integrating the log-likelihood over time, after setting the initial condition as the log-likelihood ratio of the prior probabilities, $\log[P(A)/P(B)]$, leads to a quantity $\log[P(A|S)/P(B|S)]$ which is greater than zero if A is more likely than B given the stimulus and less than zero otherwise. Thus, from standard Bayesian theory, the optimal procedure is to choose A or B depending on the sign of the summed, or in the continuous limit, integrated, log-likelihood ratio.

In the free-response paradigm, a stopping criterion must be included. This is achieved by setting two thresholds for the integrated log-likelihood ratio, a positive one ($+a$) for choice A and a negative one ($-b$) for choice B. The further the thresholds are from the origin, the

Decision-Making, Models, Fig. 2 The drift-diffusion model (DDM). The DDM is a one-dimensional model, so the two competing inputs and their noise terms are first combined: in this case $S = S_1 - S_2$ and $\sigma^2 = \sigma_1^2 + \sigma_2^2$

Decision-Making, Models, Fig. 3 The drift-diffusion model is a Wiener process (one-dimensional Brownian motion) with absorbing boundaries. In the absence of the boundaries, the probability distribution is Gaussian, centered at a distance St from its starting point with variance increasing as $\sigma^2 t$

lower the chance of error, but the longer the integration time before reaching a decision. Thus, the thresholds reflect the fraction of errors that can be tolerated, with $a = \log \frac{\beta}{1-\alpha}$ and $b = \log \frac{\alpha}{1-\beta}$ where α is the probability of choosing A when B is correct and β is the probability of choosing B when A is correct.

The Models

Accumulator Models

The first models of decision making in humans or animals were accumulator models, sometimes called counter models or race models. In these models, evidence accumulates separately for each possible outcome. This has the advantage that if many outcomes are possible, the models are simply extended by addition of one more variable for each additional alternative, with evidence for each alternative accumulating within its allotted variable. In the interrogation paradigm, one simply reads out the highest variable, so the choice depends on the sign of the difference of the two variables in the TAFC paradigm. Thus, if the difference in accumulated quantities matched the difference in integrated log probabilities of the two types of evidence, such readout from an accumulator model would be equivalent to an SPRT, so would be optimal.

In the free-response paradigm, accumulator models produce a choice when any one of the

accumulated variables reaches a threshold, so these models can be called “race to threshold models” or simply “race models.” The original accumulator models included neither interaction between accumulators nor ability for variables to decrease. However, for decisions in nature or in laboratory protocols, evidence in favor of one alternative is typically evidence against the other alternative. This is particularly problematic in the free-response paradigm, because the time at which one variable reaches threshold and produces the corresponding choice is independent of evidence accumulated for other choices. Thus, the behavior of simple accumulator models is not optimal. Comparisons of response time distributions of these models with behavioral responses showed the models to be inaccurate in this regard – observed response time distributions are skewed with a long tail, whereas the response times of accumulator models were much more symmetric about the mean. These discrepancies led to the ascendance of Ratcliff’s drift-diffusion model (Ratcliff 1978).

The Drift-Diffusion Model

The drift-diffusion model (DDM) is an integrator with thresholds (Fig. 2), or more precisely, the decision variable, x , follows a Wiener process with two absorbing boundaries (Fig. 3). It includes a deterministic (drift) term, S , proportional to the rate of incoming evidence and a

diffusive noise term of variance σ^2 , which produces variability in response times and can lead to errors:

$$\frac{dx}{dt} = S + \sigma\eta(t)$$

where $\eta(t)$ is a white noise term defined by $\langle\eta(t)\eta(t')\rangle = \delta(t - t')$.

If the model is scaled to a given level of noise, then its three independent parameters are drift rate (S) and positions of each of the two **thresholds** (a , $-b$) with respect to the starting point. When the model was introduced, these parameters were assumed fixed for a given subject in a specific task. The threshold spacing determines where one operates in the speed-accuracy trade-off, so it can be optimized as a function of the relative cost for making an incorrect response and the time between trials. Any starting point away from the midpoint represents bias or prior information. The drift rate is proportional to stimulus strength.

With fixed parameters, which could be fitted to any subject's responses, the DDM reproduces key features of the behavioral data: notably the skewed shape of response time distributions and the covariation of mean response times and response accuracy with task difficulty. Skewed response time distributions arise because the variance of a Wiener process increases linearly with time – responses much earlier than the mean response time, when the variance in the decision variable is low, are less likely than responses much later, when the variance in the decision variable is high. A more difficult perceptual choice is represented by a drift rate closer to zero, which increases response times and increases the probability of error. Such covariation of response times with accuracy matches behavioral data well, so long as an additional processing time is added to the model – the additional time representing a variable sensory transduction delay on the input side and a motor delay on the output side, both of which contribute to response times in addition to the processing within any decision circuit.

While the original DDM included trial-to-trial variability through the diffusive noise term,

additional trial-to-trial variability in the parameters was needed to account for differences between the response time distributions of correct trials from those of incorrect trials. With fixed parameters and no initial bias, the DDM produces identical distributions (though with different magnitudes) for the timing of correct responses and errors. However, response times of human subjects are typically slower when they produce errors, unless they are instructed to respond as quickly as possible, in which case the reverse is true. These behaviors are accounted for in the DDM by including trial-to-trial variability in the drift rate and/or the starting point. Trial-to-trial variability in drift rate leads to slower errors, as errors become more likely on those trials when the drift rate is altered from its mean toward zero and mean responses are longer. Trial-to-trial variability in the starting point leads to faster errors, as errors become more likely on those trials in which the starting point is closer to the error boundary, in which case the response is faster. Error response times are reduced more by such variability than are correct response times since the correct responses include more of the trials started at the midpoint where mean times are longer.

Prior information or bias can be incorporated in the drift-diffusion model, either through a shift in the starting point of integration or an additional bias current to the inputs to be integrated. A shift in starting point is more optimal and has led to two-stage models, where the first stage sets the starting point from the values of the two choices, before a second stage of integration toward threshold commences. Such a model is supported by electrophysiological data (Rorie et al. 2010).

The Leaky Competing Accumulator Model

The leaky competing accumulator (LCA), introduced by Usher and McClelland (2001), was suggested to be in better accord with neural data and to better fit some behavioral data than the DDM. The LCA is a two-variable model, with each variable integrating evidence in support of one of the two alternatives in a TAFC task. The model includes a “leak” term, as decay back to baseline for each individual variable in the absence of incoming evidence. The “competition”

in LCA is a cross-inhibition between the two variables, thus improving upon original accumulator models in allowing evidence for one variable contributing to a reduction in the other variable (Fig. 4).

$$\tau \frac{dX_1}{dt} = S_1 - kX_1 - \beta X_2 + \sigma_1 \sqrt{\tau} \eta_1(t)$$

$$\tau \frac{dX_2}{dt} = S_2 - kX_2 - \beta X_1 + \sigma_2 \sqrt{\tau} \eta_2(t)$$

The difference in the two LCA variables, $X_d = X_1 - X_2$, follows an Ornstein-Uhlenbeck process:

$$\tau \frac{dX_d}{dt} = S_d - kX_d + \beta X_d + \sigma_d \sqrt{\tau} \eta(t)$$

where $S_d = S_1 - S_2$ and $\sigma_d = \sqrt{\sigma_1^2 + \sigma_2^2}$. It should be noted that the DDM is retrieved as a special case of the LCA, if the coefficient of the term linear in X_d , that is, $\beta - k$, is set to zero.

If the only criterion for choosing the best model were its match to behavioral data, one could use Akaike information criterion or Bayesian information criterion to assess whether inclusion of a nonzero term in the LCA is justified by the better fit to data so produced. As well as ability to fit human response times, the ability for a model

to match neural activity and to be generated robustly in a neural circuit should be considered when assessing its value and relevance. One achievement of the LCA is to reproduce an initial increase in both variables, before the competition between variables causes one variable to be suppressed, while the other variable accelerates its rise. Such behavior matches electrophysiological data recorded in monkeys during perceptual choices – in particular, firing rates of neurons representing the response not chosen increase upon stimulus onset before they are suppressed (cf. trajectories in Fig. 6).

Neural Network Models and Attractor States

Some of the first models of perceptual categorization, which have had significant impact on neuroscience, were Hopfield networks, Cohen-Grossberg neural networks, and Willshaw networks. While these models are primarily aimed at formation and storage of memories, the retrieval of a memory via corrupted information is identical to a perceptual decision.

A correspondence between memory retrieval and decision making should not be surprising, since Ratcliff's introduction of the DDM – the archetype of decision-making models – was within a paper entitled “A theory of memory retrieval.” Ratcliff was focused on fitting response times and thus produced an inherently dynamical model; memory retrieval was treated as a set of parallel DDMs, each representing an individual item with a “match” and “non-match” threshold to indicate its recognition or not. The rate of evidence accumulation in each individual DDM was set in terms of the similarity between a current item and one in memory.

Models such as those of Hopfield respond to the match between a current item and memories of previously encoded items, which are contained within the network as attractor states. The network's activity reaches a stable attractor state more rapidly if the match is close. The temporal dynamics of memory retrieval or pattern completion, which comprises the decision process, is not addressed carefully in neural network models, in which neural units can be binary and time can be discretized, since this is not their goal. However,

Decision-Making, Models, Fig. 4 The leaky competing accumulator (LCA) model. Two separate integration processes for the two separate stimuli produce two decision variables, X_1 and X_2 . A “leak” term proportional to k causes a decay of the decision variable through self-inhibition, while a cross-inhibition term proportional to β produces competition. In the interrogation paradigm, a decision is made according to the greater of X_1 or X_2 at the response time, while in the free-response paradigm, a choice is made when one decision variable first reaches its threshold (given as $+a$ and $+b$, respectively)

the use of attractor states to represent the outcome of a decision or a perceptual categorization has achieved success in biophysical models based on spiking neurons (Wang 2008), albeit with far simpler attractor states than those of neural networks.

Biophysical Models

The LCA model (Usher and McClelland 2001), being motivated by neurophysiology, is similar in spirit to the more detailed biophysical models that followed it. In particular, the first model of decision making based on spiking neurons assumes two competing integrators, where integration is produced through tuned recurrent excitation and competition is the result of cross-inhibition between the pools of neurons (see Fig. 5). However, when even the most elementary properties of spiking neurons are taken into account, a few additional complications arise (Wong and Wang 2006).

First, neurons emit spikes as a point process in time, so that even at a constant firing rate they supply a variable current to other cells. The variability in the current can be reduced with an increase in the number of cells in a group, so long as the spike times are uncorrelated – that is, cells are firing asynchronously. Asynchrony is most easily achieved when neurons spike irregularly, a feature produced by adding additional noise to each neuron in the decision-making circuit. So, in accord with most likely realizations of

Decision-Making, Models, Fig. 5 A neural circuit model of decision making. Integration of stimuli ($S1$, $S2$) by groups of neurons with rates $r1$ and $r2$ can be achieved through strong excitatory recurrent connections within groups (looped connections with arrows). The mean firing rate of cells in the inhibitory pool (“INHIB”) increases with both $r1$ and $r2$, producing competition through inhibitory input to both cell groups (solid circles) (Wang 2002)

a decision-making circuit in vivo, biophysical models introduce additional noise into the decision-making model itself, which inevitably adds to any already-present stimulus noise (Wang 2002).

Second, neurons are either excitatory or inhibitory, so in order for two groups of cells with self-excitation to inhibit each other, at a minimum, a third group of inhibitory cells must be added. The need for an extra cell group to mediate the inhibition adds a small delay to the cross-inhibition compared to self-excitation, though this effect can be counteracted with fast responses in the synaptic connections to and from inhibitory cells versus slower synaptic responses in excitatory connections. The second effect of an intermediate cell group is to add the nonlinearity of the inhibitory interneuron’s response function into the cross-inhibition. Thus, the inhibitory input to one excitatory cell group is not a linear function of the firing rate of the other cell group. The consequences of this and other nonlinearities are discussed further below.

Third, biophysical models of neurons, just like neurons in vivo, respond nonlinearly to increased inputs. Similarly, synaptic inputs to a cell saturate, so are a nonlinear function of presynaptic firing rates. In the LCA model (Usher and McClelland 2001), both the neural response and the feedback are linear functions passing through the origin, so via the tuning of one variable, the two curves can match each other and produce an integrator. Integrators require such a matching of synaptic feedback to neural response so they can retain a stable firing rate in the absence of input – the firing rate produced by a given synaptic input must be exactly that needed to generate the same synaptic input – and this must be true for a wide range of firing rates. Such matching of synaptic feedback to neural response produces a state of marginal stability, typically called a line attractor or continuous attractor.

However, in the absence of symmetry or a remarkable similarity in the shape of neural response curves and synaptic feedback curves, the nonlinear curves of biophysical neurons intersect at no more than three points (Fig. 6), leading to the possibility of two discrete stable attractor

Decision-Making, Models, Fig. 6 Nonlinearity of neural response functions produces stable fixed points, toward which neural activity evolves. Nullclines are represented by the *solid thick red/green lines*, the green line where $dr_2/dt = 0$ at fixed r_1 and the red line where $dr_1/dt = 0$ at fixed r_2 . Crossings of the lines are fixed points of the system, with stable fixed points denoted by *solid black circles*. Decision states are stable fixed points with $r_2 > r_1$ or $r_1 > r_2$. As a symmetric input current is added to the network, the spontaneous “undecided” state, that is, the fixed point of low rates with $r_1 = r_2$, becomes

unstable, so that by $I_1 = I_2 = 10$, the only stable fixed points correspond to one choice or the other and a decision is forced. With high enough applied input current, $I_1 = I_2 = 15$, a new symmetric stable state appears at high firing rates, but this plays no role in the decision-making process. Deterministic trajectories from a range of starting points are indicated by the *thin colored lines* that terminate at a fixed point. See Table 1 for an *xppaut* code that produces the nullclines and Table 2 for the Matlab code that produces the trajectories

Decision-Making, Models, Fig. 7 Stochastic noise in the simulation produces trial-to-trial variability in the neural responses. With the same neural circuit of Fig. 6, addition of noise can cause neural activity to end up in different states, even with the same starting points. *Small colored dots* indicate trajectories, with *black solid circles* denoting end points after 5 s. All simulations begin with $r_1 = r_2 = 0.1$ Hz. *Far left*: with no applied current, neural activity is maintained near the low-rate spontaneous state. *Center left*:

with moderate applied current, noise can induce transitions to one of the two “decision states.” *Center and far right*: with increased applied current, trajectories always end up at a decision state – even with $I_1 = I_2 = 15$, the two decision states are more stable than the symmetric high-rate state (*far right*). See Table 1 for an *xppaut* code that produces the nullclines and Table 2 for the Matlab code that produces the trajectories

states for a group of cells (with an unstable fixed point in between). When two such groups are coupled, such as by cross-inhibition, the network can have at most four stable states, given by the combinations of low and high firing rates for the two groups. In the winner-takes-all model of decision making, three of these states can be stable in the absence of input: the state when both cell

groups have low or spontaneous activity and the two states with just one of the cell groups possessing high activity. The fixed point with both groups possessing high activity is unstable. In the presence of input, the symmetric low-activity state becomes unstable, and only two stable states remain: the decision states with one group active (“the winner”) and the other group

Decision-Making, Models, Fig. 8 A bias in the inputs causes neural activity to favor one decision state over the other, though noise means that “errors” can arise. *Left*: in the deterministic system, more trajectories terminate at the attractor point of high r_1 , because group 1 receives higher input current. In particular, a symmetric initial condition ($r_1 = r_2$) results in termination with high r_1 and low r_2 . That

is, the basin of attraction for the state with $r_1 > r_2$ includes the line $r_1 = r_2$. *Right*: with added noise, some trials with a symmetric starting point terminate in the state with high r_2 – these correspond to “errors” in the standard terminology of decision making. See Table 1 for an *xppaut* code that produces the nullclines and Table 2 for the Matlab code that produces the trajectories

Decision-Making, Models, Fig. 9 In a noisy system, the initial state can remain deterministically stable, but responses terminate in one of the decision states, with the bias favoring one final state over the other. *Left*: in the absence of noise and a bias in the inputs, more trajectories evolve to the fixed point favored by the input, but many terminate at the “undecided” state. *Right*: with added noise and symmetric initial conditions, most otherwise

“undecided” responses switch to the decision state favored by the input bias (corresponding to “correct” responses), while a few terminate in the other decision state (“incorrect” responses) and one remains in the symmetric low-rate state (an “undecided” response). See Table 1 for an *xppaut* code that produces the nullclines and Table 2 for the Matlab code that produces the trajectories

inactive (“the loser”). Importantly, with a combination of slow synaptic time constants (NMDA receptors with a time constant of 50–100 ms are an essential ingredient of the model) and sufficient fine-tuning of parameters of the network, the time course for the network’s activity to shift from the unstable initial state to one of the two remaining

stable attractor states is slow enough to match neural and behavioral response times.

Extension of Models to Multiple Choices

Many decision-making models for TAFC are simply extended to the case of multiple alternatives (Bogacz et al. 2007b; Furman and Wang 2008;

Decision-Making, Models, Fig. 10 Models for decision making with multiple alternatives. *Left:* extension of the leaky competing accumulator model to multiple alternatives, such that the negative feedback is proportional to the

sum of multiple decision variables. *Right:* extension of the biophysical model, in which cells providing inhibitory feedback are activated by the summed activity of multiple groups of excitatory cells

Niwa and Ditterich 2008; Ditterich 2010). Electrophysiological data suggests that neural firing rates reach a threshold independent of number of alternatives, but neurons receive greater inhibition, as revealed by reduced firing rates in their initial, spontaneous activity state (Churchland et al. 2008; Churchland and Ditterich 2012). This is akin to a reduction in the prior probability of each individual choice alternative before stimulus onset, if prior probability impacts the starting point of integration. Models in which the total amount of inhibition depends on the total number of alternative choices (see Fig. 10) reproduce such behavior. One consequence of the increased inhibition is a slowing of decision times as the number of alternatives increases.

Sequential Discrimination, Context-Dependent Decisions, and Prior Information

The most developed dynamical models of decision making pertain to the identification of an incoming sensory stimulus or the comparison of two or more concurrent stimuli. However, many decisions require a comparison of successive stimuli, and even when two stimuli are concurrent, our attention typically switches from one to the other when making a perceptual choice. Thus, models of decision making have been developed in which the stimuli are separated in time, so a form of short-term memory is required, with the contents of short-term memory and a later sensory input both affecting the choice of action (Romo

and Salinas 2003; Machens et al. 2005; Miller and Wang 2006). The process of making a decision by combining short-term memory, which can represent the current “context” (Salinas 2004), with sensory input provides the essential ingredient for working memory tasks and for model-based strategies of action selection (Deco and Rolls 2005).

Prior information can make one response either a more likely alternative or a more rewarding alternative given ambiguous sensory information and can lead to across-trial dependences in decision-making behavior. Consideration of how much to weigh prior information compared to the current stimulus requires a separate choice (Hanks et al. 2011), which establishes how long one should continue to acquire sensory input. Such a choice is akin to setting a decision-making threshold. Factors affecting the optimal period for obtaining sensory input include the relative clarity of incoming information compared to the strength of the prior (Deneve 2012), as well as the intrinsic cost of a reduced reward rate when taking more time to decide (Drugowitsch et al. 2012). At some point in time, awaiting further sensory evidence does not improve one’s probability of a correct choice sufficiently to warrant any extra delay of a potential reward. Solution by dynamical programming (Bellman 1957) of a model that takes into account these factors suggests that monkeys respond according to an optimal, time-varying cost function (Drugowitsch et al. 2012).

Decision-Making, Models, Table 1 A code base on xppaut to produce nullclines and fixed points for two interacting groups of neurons, connected in a decision-making circuit, as used to produce Figs. 6, 7, 8, and 9.

```

Testing Decision-Making Models

Decision-making models can be tested more stringently using tasks in which the stimulus is not held constant across the time allotted for producing a response (Zhou et al. 2009; Stanford et al. 2010; Shankar et al. 2011; Rüter et al. 2012). For example, in models such as the DDM based on perfect integration, if a stimulus is altered or even reversed for a short amount of time, so long as the stimulus alteration is in the period of its integration, it has the same effect on

response time and choice probability whether it is early or late. However, in models where the initial state is unstable, a late altered stimulus has weaker impact on the decision-making dynamics than an early one. Conversely, in models where the initial state is stable, such as the LCA with a positive leak term, only stimuli presented shortly before the final response contribute to it; the time constant of the drift term that draws the decision variables back to the initial state corresponds to a time constant for the forgetting of earlier evidence.

Decision-Making, Models, Table 2 The Matlab function used to simulate multiple decision-making trials as plotted in each panel of Figs. 6, 7, 8, and 9.

```
function[ r1 r2 ] = WTAtrials( Iapp1,Iapp2,sigma );
% WTAtrials produces multiple trials of a winner-takes-all network produced
% by coupling two sigmoidal firing rate models, each representing a neural
% population.
% Iapp1 and Iapp2 are the respective current inputs to the 2 populations.
% sigma is the level of noise (added independently to each population).
% The function returns the firing rate as a function of time for each
% trial for each population.
% Number of trials is defined within the function as Ntrials = 10.

dt = 0.001;           % timestep for simulation
tmax = 5.0;           % max time for integration
tvec = 0:dt:tmax;     % time vector

Ntrials = 10;

r1 = zeros(Ntrials, length(tvec)); % records rate of one cell group
r2 = zeros(Ntrials, length(tvec)); % records rate of other cell group

tau = 0.05;           % time constant (cf NMDA receptors)

rmax = 100;           % max rate of cells
Ithresh = 50;         % input needed for 1/2-max firing
Idelta = 20;          % determines steepness of sigmoidal f-I curve

wself = 1;            % recurrent excitatory feedback
wcross = -0.2;        % strength of cross-inhibition

trial = 0;
rhighstart = 0*rmax;  % If nonzero, provides a range of starting points.
for trial = 1:Ntrials
    if( trial <= Ntrials/2 )
        r1init = 0.1+rhighstart*(Ntrials/2-trial)/(Ntrials/2-1);
        r2init = 0.1;
    else
        r2init = 0.1+rhighstart*(Ntrials-trial)/(Ntrials/2-1);
        r1init = 0.1;
    end

    % Implement initial conditions
    r1(trial,1) = r1init;
    r2(trial,1) = r2init;

    % Produce independent random noise for each population
    noise1 = sigma*sqrt(dt/tau)*randn(size(tvec));
    noise2 = sigma*sqrt(dt/tau)*randn(size(tvec));

    % Now integrate with basic Euler-Maruyama method using sigmoid f-I
    % curves and current, I, linear in rate.
    for i = 2:length(tvec)
        r1(trial,i) = r1(trial,i-1) + ...
            dt/tau*( rmax/(1+exp(-(Iapp1+wself*r1(trial,i-1)+ ...
            wcross*r2(trial,i-1)-Ithresh)/Idelta))-r1(trial,i-1) )+ ...
            noise1(i);
        r2(trial,i) = r2(trial,i-1) + ...
            dt/tau*(rmax/(1+exp(-(Iapp2+wself*r2(trial,i-1)+ ...
            wcross*r1(trial,i-1)-Ithresh)/Idelta))-r2(trial,i-1) )+ ...
            noise2(i);
    end
end
end
```

Alternatively, if one sets up a task in which noise in the stimulus, controlled by the experimenter, is the dominant noise source in the decision-making process, one can analyze separately correct trials and error trials and align them by either time of stimulus onset or time of response to assess the impact of noise fluctuations on choice probability or response times. Care must be taken when aligning by response times, since threshold crossings are inevitably produced by noise fluctuations in the direction of the threshold crossed. However, in all cases, model predictions can be tested with experimental measurements. Current results appear to be task dependent, as some data sets suggest all evidence is equally impactful (supporting a perfect integrator) (Huk and Shadlen 2005; Brunton et al. 2013), while others suggest the weighing of sensory evidence is higher early (Ludwig and Davies 2011) or higher late (Cisek et al. 2009; Thura et al. 2012) or oscillatory (Wyart et al. 2012) across stimulus duration.

Beyond Discrimination: Action Selection

In the models considered heretofore, the decision of what action to take has been equivalent to the question of what is perceived. This is because in the relevant tasks, the difficulty is in unraveling the cause of a sensory input, which has been degraded either at source, or through sensory processing, or as a result of imperfections of memory encoding and recall. The requisite action given a sensory percept is either via a straightforward instruction for human subjects or produced by weeks to months of training in nonhuman animal subjects. Thus, in the post-training stage used to acquire data, the step from percept to action can be considered very fast and independent of the parameters varied by the experimenter to modify task difficulty.

However, most decisions require us to select a course of action given a percept or given a combination of percepts. Two general strategies, termed model based or model-free (Dayan and Daw 2008; Dayan and Niv 2008), are possible for action selection. Model-based strategies require an evaluation of all possible consequences, with their likelihood, similar in a chess

game to calculating all the combinations of moves in response to one move, or, conversely, all the possible causes of an observation. A model-free system simply learns the value of a given state and selects an action based on the immediately reachable state with highest value. For example, one could move a chess piece to produce the pattern of pieces that has led to most games won in the past.

A wide literature in the field of reinforcement learning (Barto 1994; Redish et al. 2007) and its possible neural underpinnings (Daw and Doya 2006; Johnson et al. 2007; Lee and Seo 2007) addresses how one can learn the value of states over multiple trials. This literature has influenced model-free biophysical models of decision making (Soltani and Wang 2008, 2010), with the principal requirement being a need for enhanced Hebbian learning when the resulting action leads to positive reinforcement, but not otherwise. The neural activity underlying the decision precedes the reinforcement signal, so in order for the appropriate synapses to be potentiated when positive reinforcement arrives, authors have suggested the activity itself remains in a persistent state of high firing rate (Soltani and Wang 2006) or a molecular “eligibility trace” of earlier activity persists through the time of the reinforcement signal (Bogacz et al. 2007a; Izhikevich 2007).

A model-based method for making a decision is more flexible and can be more accurate, but in all but the simplest cases, the combinatorial explosion of alternatives becomes unwieldy and time-consuming to calculate. Hierarchical reinforcement learning renders such models more manageable (Barto and Mahadevan 2003; Ito and Doya 2011; Botvinick 2012).

Wake Forest School of Medicine, Winston-Salem,
NC, USA

Synonyms

Action planning; Action selection; Motor intention; Motor preparation; Motor set; Preparatory set; Response planning; Response selection

Definition

“Motor planning” refers to the cognitive operations that are antecedent to the execution of a voluntary, goal-directed motor act or sequence.

Detailed Description

As the term implies, *motorplanning* refers to the mental operations that precede the initiation of a voluntary motor act. Imagine, for example, the simple act of reaching to pick up a glass of wine while dining at a restaurant. If you are like most people, you have just envisioned yourself making a deliberate reach to pick up the glass, presumably for the eventual purpose of taking a sip. Now, instead imagine that this same glass of wine is teetering due to an inadvertent bump of the table by a passing waiter. It is readily apparent that your reaching movement in this circumstance, though requiring the same basic excursion, would be substantively different in both its intended purpose and, accordingly, in the manner in which it is executed. Intuitively, the most likely distinction between a reach intended to take a sip of wine and one designed to prevent it from spilling is that the latter would need to be executed much more rapidly if it is to have any chance of producing a successful outcome. From the perspective of neural computation, the difference between the two

movements would at first glance seem rather trivial – reaching faster simply requires that a “stronger” neural command be provided to the relevant musculature – but, in fact, deeper consideration of what would constitute an effective motor plan in each case reveals that the problem is not at all simple from a neural coding perspective.

As is generically true for any “plan,” a motor plan is a prescription for action that is informed by current circumstances and with an eye toward an expected, future outcome. If considered as a series of mental events, the “plan” then is what occurs *after* one has decided what to do (e.g., take a sip of wine) but *before* one actually does it; by definition, a plan can be canceled, thus resulting in no action. As detailed in another entry in this section (see ► “Perceptual Decision-Making”), this depiction of mental events as discrete and serial is unlikely to have a direct correspondence in neural processing stages (see also Requin et al. 1988; Cisek and Kalaska 2010), but it is of heuristic value for considering the formulation of a motor plan as a problem of neural computation. With this in mind, it is a simple matter to consider how the motor plans for the aforementioned hypothetical scenarios must differ on the basis of presumed input and desired output. Clearly, a motor plan developed to take a taste of wine is guided by very different sources of information than that for stabilizing the unsteady glass. In the former case, the decision, and consequently the plan, to reach for the glass is informed primarily by a host of appetitive and social cues, while in the latter, visual (swaying motion of the glass) and tactile (vibration of the table) motion cues would likely predominate. In addition to receiving input from vastly disparate sources, the ensuing motor plans must evolve to produce outputs that optimize different movement parameters. Ideally, a reach to drink the wine would be graceful, or at least sufficiently precise, so as to avoid knocking over the salt shaker or dipping one’s sleeve in the olive oil intended for dipping bread. In contrast, grace may be sacrificed in the name of urgency when attempting to prevent a spill. Here, in addition to moving with greater speed, a more direct hand path to the glass (salt shaker be damned!) might be more effective. It goes without saying that if the

respective motor plans are to specify movements having different speeds and trajectories, their corresponding neural correlates must carry information that can be translated into the appropriately distinct dynamical signals at the effector level (e.g., force, joint torque).

Along with providing a general sense for what a motor plan is, the juxtaposition of these real-world reaching scenarios makes a crucial point: motor planning, and the neural that implements it, represents a flexible interface that ties internal and external cues to motor effectors in a way that ensures that actions are appropriate to context. Once again, if motor planning could be thought of as a discrete computational stage, it is one that must be receptive to all manner of possible input and capable of producing a widely varied range of output – a formidable computational problem to be sure.

Experimental Investigation

The preceding section provides a highly descriptive account of motor planning, making use of a concrete example to generate some intuition about its implications for behavior and the neural activity that underlies behavior. In the laboratory, neurophysiological studies of motor planning have a long history, and our understanding has relied extensively on behavioral tasks that incorporate what is known as an “instructed delay period,” sometimes simply referred to as the “delay period” or “instructed delay.” (The term “delay period” in this context should not be confused with its use to refer to a memory retention interval (e.g., see Funahashi et al. 1989). The delay period is the interval of time that elapses between two task instructions. The first instruction comes in the form of a sensory cue informing the subject about *what* to do and the second (the “go signal”) instructs the subject *when* to do it. In principle, the delay period is a window of time during which the subject can perform the necessary perceptual evaluation of the instruction and subsequently formulate aspects of the motor plan (e.g., select the appropriate response, specify metrics), all in advance of receiving the instruction to execute the

action. Crucially, the time allowed for advance preparation contrasts with standard reaction time tasks, in which the go signal and the informative sensory cue are simultaneous, so perceptual judgment and motor planning processes are all completed within the reaction time interval. The temporal expansion of processing time that is afforded by the delay period has been oft exploited in neurophysiological studies of the covert cognitive processes that lead to an overt motor response.

Traditionally, single-neuron electrophysiological studies of motor planning have concentrated on the activity associated with either saccadic eye movements or reaching movements of monkeys trained to direct movements toward visual goals. Superficially at least, the neural activity recorded in association with performance of a “delayed saccade” or “delayed reaching” task is strikingly similar. Whether recorded in saccade-specific or reach-specific brain regions, a substantial fraction of neurons display two temporally discrete periods of activation, one linked to the initial stimulus indicating the movement goal (sensory event) and another to the motor response (saccade or reach). Interposed between these event-linked bursts of activity is the so-called delay period activity, a major focus of neurophysiologists’ attempts to understand how motor planning is represented in the activity of single neurons. Consistent with the logic of the instructed delay task, activity during this period demonstrates the hallmark features of that which would constitute a plan for action. First, such activity reflects the vector of the upcoming movement well in advance of the imperative signal to actually produce it (i.e., the go signal). And second, as mentioned earlier, such delay period representations of future movement need not lead to execution – plans can be canceled – as has been convincingly demonstrated with behavioral tasks that later “countermand” the initial instruction of “what to do.” That the specification of movement parameters in neural activity does not inevitably lead to the initiation of movement firmly supports the interpretation of such pre-movement activity as a motor *plan* and not a motor *command*.

Specificity of Motor Plans

The question of precisely what information is being represented in motor planning activity can be a difficult one, particularly so for the skeletomotor system where it is not entirely clear what movement parameters are being optimized upon execution (e.g., see Shenoy et al. 2013). For example, returning to the example of how to plan movements of different speed, one would not be particularly surprised if *during* movement execution, the concurrent activity of motor-related neurons displayed different firing rates in association with movements of different speed. But is there a neural correlate of the *intention* to move at a certain speed? More specifically, could one predict from *delay period* activity whether an impending movement will be fast or slow? Indeed one can, as shown in an elegant study by Churchland and colleagues (2006; see also Cisek 2006) that exemplifies the way in which different intentions may manifest as differences in neural activity. In this experiment, monkeys were trained on an instructed delay task to make either a high- or low-velocity reach depending on the color of the target to be acquired. Single-neuron recordings from dorsal premotor and primary motor cortex revealed that, along with representing the vector of the upcoming movement, the delay period activity of individual motor cortical neurons was strongly modulated by the instructed speed of the reach. Though clearly demonstrating a neural correlate of planned speed, the relationship was not a simple one; the activity of individual neurons could be positively *or* negatively modulated by the intention to make a faster movement, and furthermore, this representation of intended speed was shown to interact with those of ostensibly orthogonal spatial dimensions like movement distance and direction.

The Churchland et al. study is but one example taken from more than three decades of work demonstrating how movement parameters ranging from low (e.g., force) to high (e.g., trajectory) level can be observed in the preparatory activity associated with limb movements (e.g., Tanji and Evarts 1976; Wise 1985; Kalaska et al. 1989; Riehle and Requin 1989; Fu et al. 1995; Crammond and Kalaska 2000). As is the case for

movement speed, it is not fully clear how the varied and sometimes redundant information concurrently present within motor preparatory activity is read out to yield the eventual motor commands. This is a rich topic and well beyond the scope of this short entry; nevertheless, it should be appreciated that current models of how plans become action are necessarily constrained by assumptions about how such signals would need to be transformed to yield the requisite downstream signals.

Planning of Eye Movements

Relative to the skeletomotor system, the oculomotor system is considerably less complex biomechanically, and as such, its study has been instrumental to deciphering how cognitive processes influence the neural activity that leads to movement. However, in contrast to reaching, introspection is not quite so valuable for considering how motor plans might differ when it comes to making saccades. Indeed, while making approximately three saccades every second, the complex decision and motor planning processes that inform one's choices of where and when to look go largely unnoticed. Yet such decisions and the plans that embody them are essential to effective interaction with the environment, whether that entails watching a movie, hitting a baseball, or just searching for one's keys on a cluttered countertop.

While it may be difficult to deduce from one's own eye movements, there is no argument that cognitive strategy, or planning, plays a major role in guiding saccade choices. In his pioneering studies of nearly a half century ago, Russian psychologist Alfred Yarbus showed (Yarbus 1967) that subjects who were viewing static images could be induced to alter their patterns of saccadic landing points simply by changing task instructions (and not the image itself). Thus, the way in which saccades interrogate a visual scene depends heavily on prior knowledge of what information needs to be gleaned from it. While many subsequent insights have come from psychophysical studies of natural visual scanning, studies attempting to expose the neural correlates of visual decision making and saccadic motor

planning have typically relied on more controlled task settings. As is the case for limb movements, the neural signature of oculomotor planning in its most fundamental form is that of a representation of impending saccade vector. Such is readily observed in single-neuron recordings from monkeys trained to perform variants of a delayed saccade task, and at least qualitatively similar spatial representations have been observed in visuo-oculomotor territories in frontal cortex, parietal cortex, midbrain, thalamus, and basal ganglia (e.g., Thompson et al. 1996; Snyder et al. 1997; Glimcher and Sparks 1992; Schlag and Schlag-Rey 1984; Schlag-Rey and Schlag 1984; Hikosaka et al. 1989). But more than simply predicting *where* the eyes will go, a correlate of *when* the eyes will move, or saccadic reaction time can also be observed in the preparatory activity of visuo-oculomotor neurons, specifically those with ties to brainstem circuits that are proximal to the extraocular muscles (e.g., Hanes and Schall 1996; Dorris et al. 1997).

Planning Versus Executing

At what point does an oculomotor plan become a commitment to action and what is the neural basis of this transition from the merely possible to the inevitable? In a compelling demonstration, Hanes and Schall (1996) tested the hypothesis that commitment to a particular saccadic choice occurs only when the preparatory activity of oculomotor neurons representing that choice (i.e., a given saccade vector) exceeds a specific or fixed threshold. They recorded from saccade-related neurons in the primate frontal eye field while monkeys performed the simple task of looking toward a single visual target presented at an eccentric location. Importantly, even when looking toward a highly salient and unambiguous goal, saccadic reaction times are known to display considerable variance. Hanes and Schall demonstrated that the fixed-threshold mechanism could account for this variance by verifying two predictions about frontal eye field saccade-related activity. First, they observed that the activity of individual neurons increased monotonically leading up to saccade onset, and just prior to saccade onset, activity

consistently attained the same level. The second prediction is a necessary consequence of the first one. If the commitment to move occurs when the increasing motor planning activity crosses a fixed threshold, then the reaction time should be inversely related to the rate at which the plan rises: shorter reaction times should correspond to motor plans that build up quickly and longer reaction times should occur when the accumulation is more gradual. Indeed, this is precisely what they observed. In an interesting variation on this experiment, Hanes and Schall also employed a countermanding version of the task wherein, on some trials, monkeys were cued to withhold the already instructed saccade. They found that trials in which the monkey was successful in withholding the eye movement corresponded to those in which the accumulating activity of frontal eye field neurons failed to achieve the putative threshold criterion – i.e., the neural correlate of a canceled motor plan.

Motor Planning Dynamics

The above-described examples from the skeletomotor and oculomotor systems convey the essence of what a motor plan is and how it is manifested in the neural activity that precedes an action. Such an account, however, fails to capture the dynamism of how motor plans are informed by perceptual events and changing internal states in the milliseconds leading up to a motor choice. As noted above, the perception-action cycle has been conceptualized as consisting of a series of discrete computational stages, a characterization that is reinforced by the way in which its neural basis has been studied. For the most part, the neural activity associated with performing a perceptually guided motor response has been examined with tasks, like the instructed delay task, that promote or even mandate serial completion of perceptual evaluation and motor planning processes. But, unlike for many laboratory tasks, perceptual information and behavioral goals are fluid in real life, and accordingly, plans may evolve in ways that reflect this ever-changing reality. As discussed at length in another entry (see ► [“Perceptual Decision-Making”](#)), the notion

that accumulating sensory evidence is manifested directly in developing motor plans (e.g., Gold and Shadlen 2000) blurs the distinction between perceptual and motor processes and hints at a more continuous interplay between perceptual evaluation and response selection. In fact, studies of perceptual decision making have consistently demonstrated that the neurons that accumulate sensory evidence in favor of a particular choice are very often the same ones that plan the action that serves as the ultimate expression of the decision/choice process (e.g., Requin et al. 1988; Gold and Shadlen 2000; de Lafuente and Romo 2006; Hernández et al. 2010). Clearly, a direct and intimate relationship between perceptual decision and motor planning makes good sense if the objective is to base actions on the most currently available information. In fact, the immediacy of this relationship is emphasized by recent studies of urgent decision making with tasks that prioritize the incorporation of incoming sensory information to guide ongoing motor plans. Remarkably, these studies suggest that motor systems may simultaneously harbor multiple and sometimes mutually exclusive motor plans until just milliseconds before a single alternative is committed to action – a conflict resolved on the basis of a timely perceptual cue (Cisek et al. 2009; Cisek and Kalaska 2010; Stanford et al. 2010). Ultimately, understanding the neural basis of motor planning will require a more complete framework for describing how perceptual and motor systems interact to affect the right action at the right time.

Synonyms

Absorbing boundary; Decision space boundary

Definition

A decision-making threshold is the value of the decision-making variable at which the decision is made, such that an action is selected or a commitment to one alternative is made, marking the end of accumulation of information.

Detailed Description

A decision-making threshold determines when a decision-making process is completed. It

represents a value of the decision variable, which in practice could be a linear combination of a set of neural firing rates, at which the accumulation of sensory evidence terminates and a response or action is chosen. In two-alternative forced-choice tasks, two thresholds exist, one for each of the two alternatives.

In models of decision making, the threshold can be either static or dynamic during an individual trial. Mathematically, a threshold is an absorbing boundary of the diffusion process for the decision variable. The time for the decision variable to reach such an absorbing boundary is the decision-making time (Fig. 1).

Static Thresholds

If the threshold is static, it determines where one is operating in the speed-accuracy trade-off. Low thresholds produce speedier responses, whereas higher thresholds increase accuracy. In particular, for the drift diffusion model, which is based on a perfect integrator, noise accumulates as the square root of time, whereas the signal accumulates linearly in time. Therefore, with large enough

Decision-Making, Threshold, Fig. 1 Two static thresholds act as absorbing boundaries for the 1D Brownian motion of the decision variable, X . The boundary reached in any particular trial determines the choice (or percept in a perceptual categorization task) with the time for the decision variable to reach the boundary making the dominant contribution to response time

thresholds resulting in long enough decision-making time, accuracy of decisions can approach 100%. Specifically, if the decision variable has an initial value of zero and thresholds are set at a and b , the two types of error rate, α (probability of choosing + when the signal, S , is $-$) and β (probability of choosing $-$ when the signal, S , is $+$), are given by (Ratcliff 1978):

$$\alpha = \frac{\exp\left(-\frac{2|S|a}{\sigma^2}\right) - 1}{\exp\left(-\frac{2|S|a}{\sigma^2}\right) - \exp\left(-\frac{2|S|b}{\sigma^2}\right)} \text{ and}$$

$$\beta = \frac{1 - \exp\left(-\frac{2|S|a}{\sigma^2}\right)}{\exp\left(-\frac{2|S|a}{\sigma^2}\right) - \exp\left(-\frac{2|S|b}{\sigma^2}\right)}$$

Notably, if thresholds are symmetric ($a = b$) with a starting point at the origin, then

$$\alpha = \beta = \frac{1}{1 + \exp\left(\frac{2|S|a}{\sigma^2}\right)}$$

which decreases exponentially with increasing threshold, a .

Prior belief can be incorporated by setting the two thresholds to be different, reducing a or b , respectively, if a positive or negative response is preferable or, more likely, according to information acquired before stimulus onset.

Response Times

Assuming a positive stimulus ($S > 0$), the distribution of response times for correct trials, $P(T^+)$, is given by

$$(1 - \beta)P(T^+) = \frac{\pi\sigma^2}{(a + b)^2} e^{-\frac{Sb}{\sigma^2}}$$

$$\sum_{k=1}^{\infty} k \sin\left(\frac{\pi ka}{a + b}\right) e^{-\frac{1}{2}\left(\frac{S^2}{\sigma^2} + \frac{\pi^2 k^2 \sigma^2}{(a+b)^2}\right)t}$$

and the distribution of response times for incorrect trials, $P(T^-)$, is given by

$$\beta P(T^-) = \frac{\pi\sigma^2}{(a + b)^2} e^{-\frac{Sa}{\sigma^2}}$$

$$\sum_{k=1}^{\infty} k \sin\left(\frac{\pi ka}{a + b}\right) e^{-\frac{1}{2}\left(\frac{S^2}{\sigma^2} + \frac{\pi^2 k^2 \sigma^2}{(a+b)^2}\right)t}$$

This leads to a mean response time of (Bogacz et al. 2006).

$$\langle T \rangle = (1 - \beta)\langle T^+ \rangle + \beta\langle T^- \rangle = \frac{a + b}{2S} \tanh\left[\frac{S(a + b)}{2\sigma^2}\right]$$

$$+ \frac{(a + b)\left[1 - e^{-\frac{S(a-b)}{\sigma^2}}\right]}{S\left[e^{\frac{S(a+b)}{\sigma^2}} - e^{-\frac{S(a+b)}{\sigma^2}}\right]} + \frac{a - b}{2S}.$$

In the symmetric condition, with $a = b$, then $P(T^+) = P(T^-)$ and the mean response times are given by

$$\langle T \rangle = \langle T^+ \rangle = \langle T^- \rangle = \frac{a}{S} \tanh\left(\frac{Sa}{\sigma^2}\right)$$

If thresholds are static, they can be set at an optimal level, by making use of the above formulae, if the statistics of the task and the relative costs of different types of error are known. In particular, if errors are costly, such as in lost time due to a long intertrial interval, it pays to use thresholds far from the decision variable's initial value.

Multidimensional Models

In models with two decision variables, a static threshold can depend either on each variable separately, independent of the value of the other variable, or on the difference between the two variables (see Fig. 2). In terms of neural circuits, the former corresponds to independent outputs from the competing groups of neurons, whereas the latter corresponds to a push-pull arrangement, such that each group excites one response while inhibiting the other. It is notable that for a two-variable integrator model with static independent thresholds (Fig. 2b), the difference in decision variables follows a single-variable integrator model, but with thresholds which collapse toward zero as the sum of the two variables increases.

Decision-Making, Threshold, Fig. 2 In models of decision making with two variables, each variable represents a simple function (like the mean) of neural firing rates. (a) If the thresholds correspond to a constant difference in firing rate, the model can map to a 1D model (Fig. 1) with static

thresholds. (b) If thresholds correspond to a constant absolute firing rate for each cell group, then a decision is made with smaller difference in rates as the sum of rates increases. This can be equivalent to a 1D model with collapsing thresholds

Dynamic Thresholds

In models of decision making with a single decision variable, dynamic thresholds can improve accuracy in tasks with fixed stimulus duration and can optimize reward accumulation in other situations where the cost for acquiring information is not constant in time (Drugowitsch et al. 2012). If thresholds are initially high, they can ensure the decision process is not terminated too quickly and evidence has time to accumulate and outweigh the noise. However, if thresholds collapse to zero by the end of the stimulus duration, they ensure a response is made and any evidence accumulated up until then contributes to the determination of that response.

Implicit in the calculation of performance of models with collapsing threshold is an assumption that the system can distinguish very small differences in the decision variable as the two thresholds converge on each other. An equivalent assumption is the system's ability to respond to very small differences in the times when the decision variable reaches one threshold versus the other, since the two thresholds reach zero simultaneously.

When the statistics of the inputs are unknown, one can optimally adjust the thresholds over the course of the decision, according to whether the inputs are strongly informative or not. Perhaps surprisingly, when the inputs are more ambiguous in their evidence for one response or another, it is optimal for thresholds to collapse quickly, enforcing a rapid response that depends little on information in the stimulus but more closely follows one's prior beliefs (Deneve 2012).

Decoding Field Potentials

Yan Tat Wong and Bijan Pesaran

[Local field potential decoding](#)

Definition

The local field potential (LFP) is believed to represent the aggregated neuronal activity of populations of neurons. LFP activity encodes information related to the control of movements as well as information about sensory and other cognitive processes. LFP decoding refers to the process of extracting features of these processes from the measured LFP signals. LFP decoding is typically performed for a brain-machine interface application to allow control of an external device such as a prosthetic limb or a cursor on a screen.

Detailed Description

Overview

Neuromotor prosthesis is a class of brain-machine interfaces (BMIs) that aims to restore lost motor function by decoding control information from neural signals. The local field potential (LFP) is one such neural signal that can be utilized. The LFP is operationally defined as the low-frequency components ($< \sim 300$ Hz) of neural activity recorded extracellularly using microelectrodes

and is generated via the summation of transmembrane currents (Buzsáki et al. 2012). There is great interest in decoding LFP activity due to the relative ease of recording and long-term stability of the signal in comparison with the spiking activity of individual neurons (Andersen et al. 2004; Hwang and Andersen 2013). Further, the LFP has been shown to be information rich and contains temporally structured information that reflects behavioral processes, such as movement planning and execution (Pesaran et al. 2002; Scherberger et al. 2005). There is mounting evidence that specific frequency bands of the LFP may reflect neuronal processes at different spatial scales (Siegel et al. 2012). Gamma band (30–90 Hz) and high gamma band (90–300 Hz) activity is hypothesized to reflect local encoding due to firing of neurons near the recording electrode (Schomburg et al. 2012). Activity in lower-frequency bands, < 30 Hz, is believed to reflect distributed processing across larger-scale circuits (Donner and Siegel 2011; Fries 2005; Pesaran et al. 2008).

Previous work has shown that the LFP can be decoded off-line to reconstruct high-dimensional upper limb kinematics (Bansal et al. 2011; Zhuang et al. 2010), 2-dimensional movement trajectories (Mehring et al. 2003), and the end goal of movements (Hwang and Andersen 2013; Markowitz et al. 2011). The LFP can also be used in conjunction with spiking activity to decode behavioral states (Aggarwal et al. 2013); however, the information content of the LFP is not necessarily dependent on spiking activity being present in the vicinity of the electrode (Flint et al. 2012a). In fact, the information conveyed via spiking and LFPs can differ in how they vary with cortical depth (Markowitz et al. 2011).

Work is now being undertaken to move LFP decoding online, with subjects controlling a cursor on a screen (Flint et al. 2012b).

Applications

Applications of LFP decoding include extracting information regarding skeletal joint angles, bone segment kinematics, and movement end goal

states. This information can then be used to control external actuators such as an upper limb prosthetic, motorized wheelchairs, speech decoders, a computer cursor on a screen, or function electrical stimulators to restore movements or paralyzed muscles.

Methods of Decoding

The LFP is a continuous time varying voltage signal and comprises a multivariate set of observations when many electrodes are recorded simultaneously. Decoding can be performed by using the amplitude of the time varying signal or by transforming the signal into a set of features. Commonly used features involve applying time frequency spectral techniques and decoding in the frequency domain (Mitra and Pesaran 1999), but other features include those based on wavelet transformations and other sparse, over-complete basis sets. To estimate the frequency spectrum, the LFP is generally assumed to be stationary over a short time window, typically 100–500 ms in duration. The window is then stepped in time allowing decoding across time. To minimize bias in the spectral estimates, the LFP can be first multiplied by one or many orthogonal data tapers before being Fourier transformed.

Decoding in the frequency domain allows for extraction of information carried at each frequency band; however, this greatly increases the number of inputs to the decoder. When decomposing N channels into M frequency bands, the number of potential inputs to the decoder increases to $N \times M$. Due to the challenge of fitting decoding algorithms in many dimensional feature spaces, the real-time demands of applications, and limitations in computing power, dimensionality reduction such as principal component analysis can be applied to the frequency transformed LFP to extract a set of modes (Markowitz et al. 2011). Feature selection can then be performed on these modes to obtain a smaller number of features that are then used for decoding.

Once the LFP has been preprocessed to give features, the features are decoded to obtain control

signals. Discrete control signals, such as selecting letters on a keyboard, can be decoded using classification algorithms such as linear discriminant analysis (Pesaran et al. 2002), the naïve Bayes classifier (Bai et al. 2007), and support vector classifiers. Continuous control signals, such as the trajectory of an arm movement, can be decoded using regression algorithms, such as linear regression (Wessberg et al. 2000), penalized linear regression (Mulliken et al. 2008), Kalman filters (Wu et al. 2006), and support vector regression (Shpigelman et al. 2009).

Advantages of the Approach

Local field potential decoding offers the advantage of improved long-term stability and ease of recording compared to decoding of action potentials generated by individual neurons. Recordings of action potentials can be difficult to acquire as neurons need to be within ~100 μm from the tip of the recording electrode (Buzsáki and Draguhn 2004). Further, action potential recordings are highly susceptible to changes in electrode characteristics due to local inflammatory responses such as the buildup of scar tissue (Polikov et al. 2005). In comparison, the LFP has proven to be easier to acquire and the information content more stable to tissue responses (Andersen et al. 2004). The low-frequency, $< \sim 300$ Hz, nature of the LFP also minimizes the sampling frequency required to acquire the signal compared to spiking activity. This greatly reduces the power consumption and data transfer requirements of the end application BMI wireless recording systems.

Limitations

The main limitation of decoding the LFP is that the integrative nature of the signal results in reduced spatial and temporal information. Currently, it is unclear whether enough information can be decoded from the LFP to control higher-dimensional devices such as an upper limb prosthetic. Finally, challenges presented by

performing spectral analysis in real time via a fully implanted device also remain to be resolved.

Deep Cerebellar Nuclei

Dana Cohen
Gonda Brain Research Center, Bar Ilan
University, Ramat-Gan, Israel

Definition

The deep cerebellar nuclei (DCN) consist of three nuclei: the fastigial (medial) nucleus, the interposed nucleus, and the dentate (lateral) nucleus. Together they form the primary output from the cerebellum. DCN excitatory neurons project to a variety of extra-cerebellar targets, whereas the inhibitory neurons project exclusively to the inferior olive. The activity of DCN neurons is shaped by massive inhibitory input from Purkinje cells in the cerebellar cortex and excitatory input arriving via the inferior olive axons – the climbing fibers – and mossy fiber collaterals carrying information from the spinal cord, the cerebral cortex, and several brainstem structures. Hyperpolarization induced by the inhibitory input actively controls plasticity in the excitatory synapses in the cerebellar nuclei. Overall, DCN neurons participate in local and global feedback and feedforward networks thus generating complex dynamics.

Detailed Description

DCN neurons can be divided into three main subcategories: excitatory projection neurons targeting a variety of extra-cerebellar structures, including the cerebral cortex via the thalamus; inhibitory projection neurons targeting exclusively the inferior olive; and local inhibitory interneurons. All types of neurons receive similar ratios of converging afferents; however, the information can differentially be processed due to cell-type-specific biophysical mechanisms. The main synaptic input to the DCN arrives from the Purkinje cells which provide 60–80% of the total number of synapses formed on DCN neurons. Recent estimates suggest a convergence ratio of about 20–50 Purkinje cells per nuclear cell which is by an order

of magnitude smaller than previously estimated (600–800 Purkinje cells per one DCN neuron). The climbing fiber collaterals constitute about 5% of DCN input, and the number of interneuron and mf synapsing on the projection neurons remains unclear. In addition to their glutamatergic and GABAergic synaptic inputs, the DCN receive a less studied serotonergic and cholinergic neuromodulatory input. Neurons in the DCN tend to fire spontaneously at rates >10 spikes/s and can modulate their firing rates in complex ways in response to either sensory or motor activation.

The DCN are classically considered relay stations that linearly integrate incoming information; however, recent advancement in cerebellar research suggests otherwise. Neuronal mechanisms such as short-term depression at the Purkinje cell–DCN neuron synapse, the occurrence of rebound response, and diversity in the convergence–divergence ratios of DCN afferents enhance the capacity of DCN neurons to perform complex computation.

DCN Networks

The Olivocerebellar Pathway: The DCN form a local closed-loop network with the inferior olive (IO) and the cerebellar cortex. The climbing fibers which are the axons of the inferior olive induce complex spikes in Purkinje cells which in turn inhibit the DCN. Then via their inhibitory projection neurons, the DCN regulate the coupling strength within IO neurons by activating GABAergic receptors near the IO dendritic gap junctions. The strength of the IO coupling influences the probability of the IO to generate an action potential in the climbing fibers. Climbing fiber collaterals innervate DCN regions in a closed-loop manner with the Purkinje cells activated by them. The one-to-one relation between the climbing fiber activity and complex spike occurrence in Purkinje cells and the strong synaptic connection formed by the climbing fiber collateral in the DCN generate a unique excitation–followed-by-inhibition activation sequence in the DCN.

The Mossy Fiber-Cerebellar Pathway: Information arriving via the mossy fibers is processed by the granule cells and then distributed by the parallel fiber system to the Purkinje cells from which it is projected to the DCN. The mossy fiber collaterals show considerable ramification and a bilateral projection pattern in the DCN thus generating complex convergence–divergence relation with the mf pathway propagating through the cerebellar cortex. Thus far, information processing rules governing the mossy fiber-cerebellar pathway remain to a large extent an enigma.

The Shaping of DCN Activation

DCN activation is shaped primarily by massive inhibitory input arriving from the Purkinje cells. Two neuronal mechanisms are responsible for regulating the effectiveness of Purkinje cell inhibition: the Purkinje cell–DCN synaptic characteristics and DCN rebound response.

The Characteristics of the Purkinje Cell–DCN Synapse: Two unique features characterize the dynamics of the Purkinje cell–DCN synapse – the short duration of its inhibitory postsynaptic current (IPSC) and short-term depression (STD).

The synapse between the Purkinje cells and the DCN has extremely fast inhibitory postsynaptic current kinetics ($\tau_{\text{decay}} = 2.5$ ms) which prevents accumulative effect of residual currents. Consequently, DCN neurons are inhibited by asynchronous Purkinje cell activity and are entrained to a synchronized subset of Purkinje cells displaying similar firing rates.

The Purkinje cell–DCN synapse displays strong STD which ranges from 30% for a 20 spikes/s input to 90% for rates >140 spikes/s. As a result, the massive Purkinje cell–DCN projection is counteracted by a nonlinear physiological mechanism which controls the dominant influence of Purkinje cells as indicated by anatomy. The STD mechanism enhances the Purkinje cell–DCN synapse sensitivity to dynamic than to steady Purkinje cell activation. The DCN remain within their active zone despite the significant depression at this synapse by intrinsically firing at high rates. The STD together with the short-

duration IPSCs generates a neuronal mechanism that enables the DCN to preferentially respond to low-rate, synchronized Purkinje cell inputs within a high-rate, stochastic background activity.

After-Hyperpolarization Rebound Response: DCN neurons respond to a hyperpolarizing current with a after-hyperpolarization rebound response, which plays a major part in most cerebellar theories; following hyperpolarization, the membrane rapidly depolarizes and is capable of producing spikes at membrane potentials lower than prior to hyperpolarization. The strength of the rebound response increases with the hyperpolarization amplitude and duration. Rebound firing endows DCN neurons with the ability to respond to inhibitory inputs with a spiking output and also to respond differently to the same input depending on the history of synaptic input. The occurrence of rebound response in normal in vivo conditions is still controversial.

Oscillations in the DCN

Occasionally, a subset of DCN neurons display highly synchronized transient epochs of coherent oscillations at a dominant frequency of 6–9 Hz during nonrhythmic movement. The source and computational relevance of these transient oscillations remains to be unraveled; however, recent findings suggest that together with the spinal cord and multiple cortical and subcortical brain regions, DCN oscillations may underlie the 6–9 Hz discontinuities detected in muscle activity during smooth slow finger movements. By generating coherent oscillations at different phase lags, this global network may limit drive to muscle at the oscillation dominant frequency, thereby reducing tremor and improving movement precision. The concept of neuronal oscillations as a biological controller is intriguing and should be further examined experimentally, computationally, and theoretically.

Summary

Over the years the DCN have received little attention in comparison to the plethora of studies which

focused on the olivocerebellar cortex system. The discovery of several complementary nonlinear neuronal mechanisms for controlling DCN neuronal activity makes it attractive to computational and experimental neuroscientists who are interested in adding the DCN to the cerebellar loop and thus develop a broader view of its function (Beitz and Chan-Palay 1979; Teune et al. 1998; Shinoda et al. 2000; Telgkamp and Raman 2002; Pedroarena and Schwarz 2003; Baumel et al. 2009; Steuber et al. 2010; Williams et al. 2010; De Zeeuw et al. 2011; Jaeger 2011; Person and Raman 2012; Uusisaari and Knopfel 2012).

Delayed Rectifier and A-Type Potassium Channels

Paul B. Manis

Otolaryngology/Head and Neck Surgery and Cell and Molecular Physiology, University of North Carolina, Chapel Hill, NC, USA

Synonyms

Definition

Voltage-gated potassium channels can be grouped into two broad categories: the delayed rectifiers and the “A-type” channels. Delayed rectifiers are named after their delay before activation commences following a voltage change and their contribution to rectification of the current-voltage relationship of cells once they are activated. Delayed rectifiers show little time-dependent inactivation. Inactivation is a process whereby the channels close without a change in the driving force. A-type potassium channels, in contrast, show prominent time and voltage-dependent inactivation. A-type channels may also activate with a delay. There are several approaches to modeling these channels. The roles that the different classes of channels may play in neuronal excitability depend on their interactions with other channels, the time course of voltage fluctuations in the cells, and their localization in the membrane. A-type potassium channels in particular can impart interesting time and voltage-dependent regulation of spike timing that can significantly affect the temporal representation of information in the nervous system.

Detailed Description

Background

Voltage-gated potassium channels are a highly heterogeneous family. Voltage-gated potassium channels appeared early in cellular evolution, and homologous channels can be even found in plants (Cherel 2004). Early voltage clamp studies in invertebrate preparations first identified the delayed rectifier conductances (Hodgkin and Huxley 1952). Subsequent studies identified potassium conductances that inactivated rapidly (Nakajima 1966; Connor and Stevens 1971), which were then termed A-type currents.

The discharge patterns of neurons result from the interplay between the membrane voltage and all of the space, time, and voltage dependence of their ion conductances. The expression of potassium conductances varies widely among neurons and is one of the main determinants of excitability and discharge patterns. However, potassium conductances, even from a single class, play multiple

roles that depend on where they are located in the cell membrane (Jensen et al. 2011). Those conductances located in the soma and axon hillock region are important for discharge pattern and spike rates. Conductances located in dendritic trees help to shape synaptic integration (Johnston and Narayanan 2008) and can contribute to bursting behavior of cells. Conductances located in the presynaptic membrane can regulate transmitter release. Thus, both delayed rectifier and A-type potassium channels can confer very different spiking patterns, subthreshold dynamics, and shaping of synaptic integration and thus are versatile tools for neural information processing.

In mammals, versatility in part results from the production of voltage-gated potassium channels by multiple gene families. Each gene family directs the production of proteins corresponding to primary subunits, auxiliary subunits, and channel-associated proteins, and each of these can have quite distinct physiological functions (reviewed in Coetzee et al. 1999; Jan and Jan 2012; Rudy et al. 2009). The delayed rectifier and A-type channels arise from that is known as the Kv family of channels. There are four broad Kv families, which in the literature are addressed by multiple nomenclatures. Kv1 (KCNA), Kv2 (KCNB), Kv3 (KCNC), and Kv4 (KCND) are the primary α -forming families. Each of the α -subunits, which have six trans-membrane domains, forms the pore-conducting portion of the channels and assembles as tetrameric protein complexes. The channel pore loop (the permeation pathway through which potassium flows) is located between the fifth and sixth trans-membrane spans of each α -subunit, and the assembly together forms a single pore. The β -subunits, which can modify channel function, associate with the α -subunits with a 1:1 stoichiometry.

Diversity in Kv channel structure arises from two principal sources. One is the existence of splice variants (in Kv1.5, Kv3.1, Kv3.2, Kv3.3, Kv3.4, and Kv4.3). The other is the way in which the tetrameric structure is assembled. The specific assembly of the channel subunits is thought to be governed by C-terminal protein interactions such that all of the subunits of a given channel must belong to a single family. Although there is some evidence for specific rules regarding assembly, the combinatorial possibilities of various α and

auxiliary subunits, as well as splice variants, can create channels with a wide diversity of voltage-dependent behavior and with the potential for specific targeting by intracellular messengers. There seems to be no evidence for posttranslational editing of these channels in mammals. However, posttranslational modifications of the channels, including glycosylation (Watanabe et al. 2003) and phosphorylation (Jones and Kaczmarek 1996; Song and Kaczmarek 2006), can significantly alter channel function.

Although the details of channel assembly are not well understood, there is evidence that assembly depends on targeting motifs in the protein that regulate channel trafficking to the membrane (Jensen et al. 2011), as well as specific interactions among subunits during trafficking through the endoplasmic reticulum (Heusser and Schwappach 2005). In addition, auxiliary subunits (beta subunits) have been shown to act as chaperones and influence the targeting and assembly of the channels, as well as gating in assembled channels. Furthermore, the localization of Kv channels can be regulated by motifs that can target the channels to postsynaptic densities. Channel localization in the membrane is not random, but is, at least for some channels, quite focal. This allows the channels to interact with other proteins and may also facilitate local modulation by short-range messengers, including calcium (An et al. 2000; Anderson et al. 2010).

The classification of ion channels is complex, much as the classification of cell types in a given brain region. A variety of factors must be considered, including the voltage dependence of activation, the kinetics of activation, the presence and speed of inactivation, and the voltage dependence of inactivation. As each of these parameters usually is represented as a continuum, the categorization is necessarily fuzzy. Furthermore, the categorization of delayed rectifiers and A-type channels does not map cleanly onto particular Kv families. For example, Kv1.4 is often considered an “A-type” channel, while Kv1.1 and Kv1.2 are delayed rectifiers. It could be argued however that the entire Kv1 family is best described as delayed rectifiers, with varying amounts of slow inactivation. Similarly, Kv3.4 is often considered “A-type,” while Kv3.1 is another kind of delayed

rectifier; however the same argument as for Kv1 might be used here, in that Kv3.4 inactivation is slow and incomplete. The three members of the Kv4 family all create channels that show rapidly inactivating currents and thus are “classical” A-type channels in this respect. The two members of the Kv2 family are delayed rectifiers and do not show inactivation.

Basis of Models

The classical models of Hodgkin and Huxley are the most commonly used formulations to represent the responses of delayed rectifier ion channels. These models provide macroscopic descriptions of conductances and have the advantage that they have been well studied and are readily implemented.

Measurements Needed to Constrain Models

In order to construct a model for a particular conductance, a number of parameters must be measured. The measurements are usually re-represented, through curve fitting, by convenient analytic functions that capture the voltage and time dependence of channel function. In many cases, these functions represent an approximation of the underlying biophysical basis for channel gating. Thus, the voltage dependence of the channel activation (and inactivation), as well as the rates that the channels open, close, and inactivate at different voltages, needs to be measured. Such measurements can only be made using voltage clamp methods and are best made on cells with few processes to improve space clamp, or using membrane patches, such as outside-out patches. The voltage dependence and rate of *activation* (channel opening) are measured by holding the cell at a negative voltage and then stepping to different voltage levels, while recording the time course of the current. The voltage-dependent rate of *deactivation* (channels returning to a closed state following a step that reduces activation) that can be used is measured at voltages where activation is weak or nonexistent by

stepping the cell (or patch) to a voltage where the channels are substantially opened and then stepping the membrane potential to a new level. The voltage dependence of *inactivation* (channels closing while the voltage is maintained at a level that would otherwise keep the channels open) is usually measured by activating the conductance and then measuring the time course of inactivation directly from the decrease in current over time with a constant driving force. An additional set of measurements of the recovery from inactivation also need to be made. Recovery can be measured by stepping the patch to a voltage that nearly fully activates the channels, holding long enough to allow them to inactivate, and then using a test pulse to measure the return of the current at various times after the end of the inactivation step, for a variety of voltages during the intermediate period (Fig. 8).

The kinetics of the channel opening are measured by direct fits of equations to the activation phase. Typically, the goal is to extract the time constants as a function of voltage, and the rising phase is sigmoidal. Thus, the activation function will be

$$A(V, t) = A_0 * \left(1 - e^{-t/\tau}\right)^+$$

where $A(V, t)$ is the current at voltage V , as a function of time following the onset of a step voltage change; A_0 is the amplitude of the current change; τ is the time constant for activation at voltage V ; and n determines the shape of the sigmoidal rise of the current and is usually an integer value between 1 and 4.

In some cases, multiple terms are needed, for example, when the activation has both a sigmoidal rise and a slow component.

Deactivation rates are determined from

$$A(V, t) = b * e^{-t/\tau}$$

Usually this single-exponential function is sufficient. However, there are some conditions where the current decay associated with the channels turning off at a new voltage may have multiple components. For example, a cell might express two populations of channels that cannot be pharmacologically isolated. Alternatively, there might

only one set of channels that have multiple energetically distinct open states or closed states. In this case, the closing rate will depend on which state a population of channels might be in at the time of the step. In intact neurons with extensive dendritic trees, multiple decay time constants may also appear, but will have an ambiguous interpretation. While such decays may represent multiple channels or states within channels, they can also result from channels located at different places in the cell that are not adequately controlled by the voltage clamp and so are not at the same voltages or state when the step is terminated.

These rates are, in all cases, aggregate rates resulting from the equilibrium rates, which are usually analyzed in terms of a two-state model:

The τ values are related to α and β as follows:

$$\tau = \frac{1}{\alpha + \beta}$$

To isolate alpha and beta, the voltage dependence of steady-state or peak activation can be measured and fit to a Boltzmann function:

$$n(V) = \frac{1}{1 + e^{-(V-V_o)/k}}$$

where $n(V)$ represents the fraction of channels open at any given time, which is also $\alpha/(\alpha + \beta)$. Following some algebraic manipulations, α and β can then be computed from the τ and $n(V)$ curves as

$$\alpha = n(V)/\tau \quad \beta = (1 - \tau * \alpha)/\tau$$

These calculations can be done for the individual voltage points. The resulting $\alpha(V)$ and $\beta(V)$ are then typically fit to exponential functions of voltage. Alternatively, the $\tau(V)$ can be fit, combining activation and deactivation kinetic measurements to a more complex function, usually of the form

$$\tau(V) = \frac{1}{a * e^{-(V-V_1)/k_1} + b * e^{-(V-V_2)/k_2}} + O$$

although any equation that adequately describes the data can be used.

Measuring Inactivation

The voltage dependence of inactivation is measured by using a series of voltage steps, usually of fairly long duration, prior to a depolarizing step that activates the channels. The peak current is then fit to a Boltzmann function to describe the steady-state inactivation. In practice, it may be necessary to also measure the voltage-independent conductances (such as residual delayed rectifiers) using a depolarizing conditioning voltage step and subtracting the two sets of traces to isolate the transient component of the current. Inactivation may be incomplete, so the function needs to include an offset parameter to account for the minimum level of inactivation. The voltage dependence of the rate of inactivation is measured by first holding at a negative potential to remove all inactivation and then stepping to various positive potentials. The decay phase of the current is then fit to a single or double exponential function, and these rates are used for the τ curves.

Problems Encountered in Making These Measurements

Technical

As already indicated, having adequate space clamp is absolutely necessary. This can be achieved by using expression systems in small cells without processes, performing acute isolations of cells, which shears off most of the processes, or by using outside out, inside out, or enucleated patches. In addition it is important to properly compensate the amplifiers so that the current measurements and time course are as accurate as possible. The best measurements are made by minimizing series resistance and electrode capacitance and using a wide-band amplifier with minimum lag settings.

Heterogeneity

When working with native channels, it is quite common to encounter heterogeneity in the responses to voltage steps. There are two sources

of heterogeneity in such measurements. The first is measurement error that arises from incorrect voltage clamp due to space clamp problems, or inadequate compensation for series resistance. The second is true biological variability, such as modifications of voltage dependence or open probability by phosphorylation. This increases the scatter in the data. This can be addressed either by averaging results from many cells (or fitting to the population data) or by identifying an underlying mechanism that causes the scatter, such as phosphorylation, and attempting to control that factor. Another approach is to fit the data from individual cells and to use the variability in subsequent modeling.

Alternative Approaches

While measurements of the macroscopic behavior of neuronal conductances are frequently sufficient to model the excitability of cells, more detailed kinetic information may be obtained from single-channel measurements.

Additional Kinetic Components

In some cases, the kinetic behavior of the channels appears to be more complex than a simple model may predict. For example, some channels show additional state-dependent transitions that appear as slow changes in open probability or multiple stages in recovery from inactivation. In this case more insight can be gained by examining single-channel currents using the same protocols described above. The incorporation of additional kinetic components requires some care and can be done either as an adjustment to an existing model or by treating the kinetic components as if they arose from a separate population of independent channels.

Computation of Models

There are several approaches that can be used for the computation of the models. The first, and most common, is to express the channel kinetics as a set of coupled differential equations and to solve those equations numerically for forcing functions that change the voltage. This is the approach used

in the examples that are shown below. A second, which can give insight into the structure of the model, is to use the Q-matrix formulation (Colquhoun and Hawkes 1995). Q matrices are useful for examining state changes in response to step perturbations. The simulations shown in Figs. 1–10 were computed using NEURON (www.neuron.yale.edu), with Python. The equations for the channels are from Rothman and Manis (2003b). For simulations with action potentials, a model of the NaV1.1 sodium channel (Barela et al. 2006) was incorporated into the model.

Examples of Delayed Rectifier Models

Example 1 Figure 1 shows an example of a voltage clamp simulation of a delayed rectifier potassium conductance, using the description of Rothman and Manis (2003a, 2003b). This is a “high-voltage” activated delayed rectifier. The voltage clamp command voltages are shown in Fig. 1c, and the resulting currents are shown in Fig. 1a, for steps up to 0 mV. The current grows nonlinearly with voltage. The channels activate rapidly, and current through the channels is sustained during the 100 msec voltage step.

Delayed Rectifier and A-Type Potassium Channels, Fig. 1 Currents and conductances for delayed rectifier potassium conductance

A tail current is visible at the end of the step (at 120 ms). Figure 1b shows the conductance of the potassium channels during the voltage step. Figure 1d shows the steady-state current-voltage relationship of the currents in Fig. 1a. The channels begin to open near -40 mV, and once activated, the currents become large with increasing voltage. Figure 1e shows the gating variables, which range from 0 to 1. There are two activation gating variables in this model, corresponding to a rapid activation (in red), and a small component with slower activation (in blue). The activation rates, as a function of voltage, are plotted in Fig. 1f for this model.

This delayed rectifier is typical of the channels that help repolarize action potentials in cortical interneurons and neurons of the auditory pathway and is associated primarily with the Kv3 (Kv3.1, Kv3.2) family of potassium channels. Note that the conductances do not activate until nearly -40 mV.

This high activation voltage suggests that the conductances will not play a role in the integration of synaptic events, but are only triggered when action potentials occur.

Figure 2 shows the time course of the delayed rectifier channel activation during an action potential, in current clamp. The current begins to activate near the peak of the action potential (indicated by the black dashed line) and reaches its peak (indicated by the red dashed line) about halfway down the falling phase of the action potential. Thus, the delayed rectifier can help repolarize action potentials.

This conductance does not show inactivation and deactivates very rapidly. Therefore, it should be available to repolarize action potentials with nearly the same conductance every time. This ability is illustrated in Fig. 3, where a high-frequency train of action potentials is elicited by

Delayed Rectifier and A-Type Potassium Channels,

Fig. 2 Activation time course of delayed rectifier channels during an action potential

Delayed Rectifier and A-Type Potassium Channels, Fig. 3

Delayed rectifier that activates in nearly the same way for every action potential in a high-frequency train

a depolarizing current pulse. The potassium conductance, plotted in Fig. 3b, is nearly the same for each action potential. The slightly smaller current associated with the first action potential is related to initial conditions and the presence of other channels in the model that affected the action potential width very slightly.

Example 2 The delayed rectifier class of channels shows variability in the activation voltage range and in the amount of inactivation that can occur. The channels in Example 1 represent one part of the spectrum and have a relatively high-voltage threshold and no inactivation. However other channels have a much lower activation-voltage range and show some inactivation. For example, the channels that help repolarize action potentials at the nodes of Ranvier in axons are largely composed of Kv1 family channels (Rasband 2010). These channels are also found in the cell bodies of some neurons, where they

play a role in the integration of synaptic events and regulate discharge patterns. As an example of these channels from this group, simulations are shown in Fig. 4 for voltage clamp of the low-voltage activated potassium conductance found in neurons of the auditory brainstem, which are composed of various mixtures of Kv1 subunits.

There are several features of the voltage clamp currents in Fig. 4a that are important to identify. First, with the model cell held at -60 mV, there is a slight outward current (visible from 0 to 20 ms). This current arises because these channels have a significant open probability at this voltage, which is close to the resting potential of typical neurons. Second, with depolarization, the current activates rapidly, but then begins to inactivate. However, the inactivation is slow and incomplete. Third, hyperpolarizing pulses turn the conductance off. At the end of a hyperpolarizing pulse, the conductance activates again, and because some of the inactivation has

Delayed Rectifier and A-Type Potassium Channels, Fig. 4 Delayed rectifier with incomplete inactivation and low activation-voltage range

been removed by the hyperpolarization, the current shows a slight peak before settling to a new equilibrium. This rebound is visible in the slight outward current between 125 and 150 ms. These features are also all visible in the conductance traces in Fig. 4b. Figure 4d shows the peak (blue) and steady-state (red) currents as a function of voltage, showing how the inactivation increases with more depolarized steps. The activation and inactivation state variables are plotted in Fig. 4e. Note that near the resting potential (-60 mV), the activation curve is already at 5–10% of the channels “open,” while the conductance is fully activated by -20 mV. Figure 4f shows the activation rate (in red), which is very fast, and the slower inactivation rate in blue. These curves have the typical voltage dependence, where the time

constants are slowest near the resting potential of the cells.

These low-voltage activated conductances often prevent cells (and axons) from firing repetitively during depolarization. This feature is illustrated in Fig. 5a. A large depolarization can initiate a single spike, and the rapid activation of this conductance (Fig. 5b) contributes to the repolarization of the action potential. In addition, the activation of the conductance generates a sustained shunting current that prevents subsequent action potentials. The voltage during the current pulse in Fig. 5a represents an equilibrium between the depolarization caused by the current step (Fig. 5c) and the outward, hyperpolarizing current generated by the conductance (Fig. 5b). This single-spike firing pattern is also typical of models using the standard

Delayed Rectifier and A-Type Potassium Channels, Fig. 5

Low-voltage activation range of some delayed rectifier channels that can suppress repetitive firing

Hodgkin-Huxley delayed rectifier, which has a similar activation voltage close to the resting potential. Note that the membrane depolarizes slightly during the current pulse, as the slow inactivation of the conductance proceeds. Cells that express high levels of this conductance are sensitive to the slope, not just the amplitude, of synaptic potentials, and the conductance can prevent action potentials from being elicited by slow depolarizations. In addition, because the conductance is active at the resting potential, cells tend to have short time constants.

Finally, we can consider the states of the channels, as a useful reminder that the total conductance is an equilibrium condition across a population of channels and that the channels exist in more than just two states (open and closed). In the Hodgkin-Huxley formulation, the activation of a channel requires a series of energetic transitions across a set of four closed states, culminating in the open state. At any given voltage, the channels are distributed across these states, in different proportions. Using the Q-matrix formulation

(Colquhoun and Hawkes 1995), we can easily see at equilibrium what this distribution is like for any given state, as shown in Fig. 6. This figure shows the distribution of channel subunit states for the model:

$$C_0 \rightleftharpoons C_1 \rightleftharpoons C_2 \rightleftharpoons C_3 \rightleftharpoons O$$

where each of the C_n refers to a population of subunits (e.g., four subunits in the “closed” state at C_0 , three at C_1 , etc.) and O refers to the open (conducting) state. Thus, at -100 mV, nearly all of the subunits are in the C_0 state, while at -20 mV, nearly all are in the O state. The voltages near rest (-70 to -50) are interesting. Here, we see that the channel subunits are in a different equilibrium, with a high probability of subunits being in the C_2 or C_3 state. Channels with subunit state distributions like this will activate very rapidly, and the activation may appear to be first order, rather than sigmoidal as might be expected. This is particularly true at -60 mV, where about 10% of the channels are

Delayed Rectifier and A-Type Potassium Channels,

Fig. 6 Residence of channel states in a multistate model that is voltage dependent

Delayed Rectifier and A-Type Potassium Channels, Fig. 7 Voltage clamp model of A-type (transient potassium) currents, based on channels from Rothman and

Manis (2003b). This channel has two different voltage-dependent inactivation rates (visible in F with different colors)

open, while just over 30% are in the C_3 state. The channels in the C_3 state only have to go through a single energetic transition to reach the open state, and thus the activation will be immediate and take on a single-exponential shape. The channels in the C_2 state (~35%) will also transit into the C_3 and O states, with those reaching the O state doing so with a second-order exponential activation (sigmoidal) function. This state-based approach is conceptual but also very useful in thinking about how channels activate or deactivate and in understanding channel behavior in the important voltage range at the cusp of activation.

Examples of A-type Potassium Channel Models

The transient potassium conductances can be modeled in the same way as the delayed rectifiers,

but with the addition of a term that describes the rate at which the channels inactivate. Inactivation was discussed briefly above with respect to low-voltage activated channels. Modeling inactivation requires the addition of a state variable and its rate constants as a function of voltage. Typically, an inactivating conductance is represented as

$$g(t, V) = g_{\max} * a(t, V)^n * b(t, V)$$

where $g_{\max}$ is the maximal conductance, a represents the activation state variable, and b is the inactivation state variable. The time evolution of a and b is computed in the same way as described for delayed rectifiers (or the Hodgkin-Huxley sodium channel), taking into account the instantaneous rates as a function of voltage. This formulation is equivalent to adding an inactivating state, but does not ascribe a particular mechanism to inactivation. Nonetheless, it often

Delayed Rectifier and A-Type Potassium Channels, Fig. 8 Time course of recovery from inactivation of A-type potassium channel model using a two-pulse paradigm

provides an acceptable description of channel behavior under a variety of conditions.

The response of a voltage-clamped cell with a rapidly inactivating potassium current (from Rothman and Manis 2003a, b) is shown in Fig. 7. Activation with depolarization is fast (Fig. 7a), but inactivation begins immediately, shutting off the conductance (Fig. 7b) and decreasing the current until the channels are nearly completely off. The peak activation is similar to that of the delayed rectifier (Fig. 7b), but the steady-state current shows only a small hump in the middle of the voltage range. The steady-state activation and inactivation curves are shown in Fig. 7e. Note that there is overlap of the curves in the -60 to -40 mV range. This overlap creates a “window” current, which causes the hump in the steady-state relationship in Fig. 7d. In this range, the channels both activate and inactivate, but there is a finite probability that some channels will be in

the open state at any time. The rate constants are shown in Fig. 7f. This particular version of the A-current had a second slow inactivation component, whose unusual voltage dependence is shown by the green curve.

After inactivation, the channels require some time at a hyperpolarized voltage to recover and become available for activation again. This is illustrated in Fig. 8a. A 100 ms voltage clamp step to -10 mV is followed at a variable delay by 10 ms steps to 0 mV. As the delay increases, the channels recover from the inactivated state, eventually reaching the same conductance that they did when activated from -60 mV. The recovery is quite fast and essentially proceeds with a single-exponential time course, beginning at the instant of repolarization. Recovery proceeds more quickly with deeper hyperpolarization between the conditioning 100 ms step and the test step.

Delayed Rectifier and A-Type Potassium Channels, Fig. 9

Time courses of A-type potassium conductance during an action potential. The activation is similar to the delayed rectifier in Fig. 2. Note that the action potential is also being repolarized by the delayed rectifier in this model

Like the delayed rectifier, the activation of the transient currents begins near the peak (Fig. 9a) of the action potential, after which the channels close quickly (Fig. 9b). During trains of action potentials, recovery from inactivation depends on the depth of the spike after hyperpolarization and the interspike interval. Thus, the contribution of transient potassium currents is highly dependent on multiple factors. In Fig. 10, a train of action potentials (Fig. 10a) is associated with variable activation of the transient current. The transient conductance decreases during the train, as channels are inactivated and there is not sufficient time for full recovery from inactivation between successive action potentials.

Biological Significance

The variety of potassium conductances contributes to a rich repertoire of firing patterns among

neurons. The details of the voltage dependence of activation and inactivation, as well as the voltage dependence of rates, all play into the functional contributions of the channels. While the repolarization of action potentials is one important function, the A-type channels in particular can have a complex effect on spike latency in many cells. Channels with a relatively negative activation and inactivation that are significantly modulated by small changes in membrane potential near and below rest are especially poised to interact with synaptic potentials and to regulate spike discharge patterns and spike latency (Kanold and Manis 1999). Indeed, interesting nonlinearities and bifurcation behavior of the spike patterns have been seen and analyzed (Meng et al. 2011). As the relative timing of spikes in neurons, even on a millisecond scale, is thought to be important in the representation of information, mechanisms that can modulate that timing are likely to play

Delayed Rectifier and A-Type Potassium Channels,

Fig. 10 Activation of A-type potassium conductance during a train of action potentials. Note that the conductance decreases during the train because of inactivation

important roles in how information is integrated in downstream neurons.

Definition

Delay-induced transient oscillations (DITOs) are oscillations that occur in bi- or multi-stable system of delayed differential equations as it

converges to one of its stable equilibria, oscillations that do not exist when the delay vanishes.

Metastable oscillations are transient oscillatory patterns (or states) that attract neighboring initial conditions and last for a “long time” almost without change. These oscillatory patterns seem to be stable: to detect their instability, it is necessary to observe the system over a seemingly endless time window. Such long-lasting transients would be undistinguishable from (nearly) periodic solutions. A mathematical definition of metastability needs a quantification of “long time”. The most common approach is to consider a one-parameter family of systems and to compare the transient time duration for different values of the parameter. For instance, if $\varepsilon > 0$ is a real parameter, then an oscillatory pattern is said to be metastable if the time duration of the transient oscillations grows exponentially as $\varepsilon \rightarrow 0$.

Long-lasting DITOs could be very important in understanding the dynamics of the system.

Detailed Description

Delays are ubiquitous and have many different sources. In neurons the delay corresponds to the time it takes for a signal to be transmitted (see entry ► “[Time-Delayed Neural Networks: Stability and Oscillations](#)”). Experimental studies of the behavior of self-connected single neurons have shown that the discharge pattern of biological neurons (Vibert et al. 1979; Diez-Martínez and Segundo 1983) can be influenced by the delay. Different ranges of delay correspond to different patterns of neural activities (an der Heiden 1981; Plant 1981; Chapeau-Blondeau and Chauvet 1992; Lourenço and Babloyantz 1994; Vibert et al. 1994; Menon 1995; Hangartner and Cull 1995; Pakdaman et al. 1996).

In some artificial neural network (ANN) applications, such as content addressable memories, information is stored as stable equilibrium points of the system. Retrieval occurs when the system is initialized within the basin of attraction of one of the equilibria and the network is allowed to stabilize in its steady state (Hopfield 1984; Hirsch 1989; Foss et al. 1996). Delayed interunit

transmissions may render some equilibria unstable, thus deteriorating information retrieval. Many studies have derived conditions that ensure that the asymptotic behavior of networks with and without delay is similar. (i) The system with delay and the system without delay should have exactly the same stable equilibria (the delay does not alter local stability). (ii) The system without delay and the system with delay are both almost convergent, so that the delay does not induce spurious stable undamped oscillations. Constraints (i) and (ii) avoid delay-induced changes in the asymptotic behavior of the system. Yet, even under such constraints, the delay may still influence important features in the system’s dynamics. For instance, the delay can alter the boundary of the basins of attraction of the stable equilibrium points of the network as shown in Pakdaman et al. (1998a). Moreover, the delay can also produce transient oscillations that end up vanishing with time. In Pakdaman et al. (1997a, 1998a), it was studied the influence of the delay on the behavior of a network composed of graded-response neurons (GRNs) forming a ring where each unit is connected unidirectionally to the next one. The GRN has constant decay rate, and its output is a sigmoidal function (for instance, tanh function) that depends on its activation. The connection is said to be *excitatory*, when the sigmoidal function is increasing, and it is said to be *inhibitory* when it is decreasing. The GRN ring network satisfies the constraints (i) and (ii), so the system will converge to one of its equilibrium points if the interunit connections are instantaneous or delayed. However, the transient regime of the system with instantaneous interunit transmission greatly differs from that of the system with delayed interunit transmission. In the case of a pair of interconnected GRNs sketched in Fig. 1, when the connections are instantaneous, the system evolves rapidly (without oscillations) to the equilibrium which basin of attraction contains the initial condition. The smaller the decay rate (charge-discharge time) of the neurons, the faster it will reach the equilibrium: the time evolution of the neuron activation x , y , represented by the solid line in Fig. 1 (graph on the right), corresponds to a pair

Delay-Induced Transient Oscillation (DITO) and Metastable Behavior, Fig. 1 Left: sketch of the system formed by two interconnected GRN (I_1 and I_2 are external inputs). Right: temporal evolution of the neuron activation

x, y in the case of identical neurons ($I_1 = I_2$) with instantaneous connections. The smaller the decay rate (charge-discharge time) of the neurons (solid line), the faster it will reach the equilibrium

Delay-Induced Transient Oscillation (DITO) and Metastable Behavior, Fig. 2 Transient oscillations when the interunit connections are delayed. The larger the delay, the longer the duration of the transient. Time is

measured in units of delay. Left: thick and thin lines represent the activations x and y , respectively. Right: larger delay, only the activation x is displayed

of neurons with decay rate smaller than the decay rate of the pair of neurons corresponding to the dashed lines in Fig. 1 (thick dashed line represents activation x ; thin dashed line represents activation y).

When the connections are delayed, the GRN activation will oscillate before converging to the equilibrium point as shown in Fig. 2 for two values of the delay. As the delay increases, the longer is the duration of the oscillations of the activations x and y . Also, as displayed in Fig. 2, the shape of the transient oscillations assumes a square-wave-like shape for large delays, the square-wave-like oscillations outlasting the

observation window. Only the a priori knowledge that the point is in the basin of attraction of one of the equilibria allows us to state that these oscillations are transient. In Pakdaman et al. (1998b), the term DITO was coined for this phenomenon both as an acronym for “delay-induced transient oscillation” and as a means to emphasize its repetitive nature.

A ring network of GRN is inhibitory only if it has an odd number of inhibitory connections. Therefore, a pair of two interconnected GRNs is excitatory when both connections are excitatory (like in Pakdaman et al. 1997a, 1998b) or both inhibitory (like in Milton et al. 2010). So the time

evolution of the activations x and y , displayed in Figs. 1 and 2, describe the behavior of a pair of reciprocally excitatory neurons or a pair of reciprocally inhibitory neurons.

Experimentalists have long recognized the importance of transients in neural behavior as a means to convey information about environmental as well as internal changes (e.g., Segundo et al. 1994). Long-lasting DITOs could strongly alter the dynamics of the system and, for instance, interfere with information retrieval in neural networks. The information contained in the transient regime is all the more important when the system evolves in rapidly changing environments where the neural networks involved in information processing do not dispose of the time lapse necessary to reach a stationary regime. Overall oscillatory patterns are frequently observed in the activity of nervous systems. Their roles are either clear as in respiration, where they control motor activity, or unexplained as in the electroencephalogram where they are apparently related to the brain information processing in a still obscure way. Oscillatory patterns are observed when units discharge periodically and synchronously. In living nervous systems, delays are ubiquitous, ranging from a few to several hundreds of milliseconds. They are due to action potential propagation along axons, synaptic delay, etc. Delay-induced long-lasting transient oscillations could thus take part in various nervous system operations: epileptic seizure, for instance, could be due to a DITO (see Milton et al. 2017 and entry ► “Dynamics of Disease States: Overview”). In ANN applications relying on the convergence of the network to a steady state, control over the transient regime is also an important issue. Large increase in the transient regime duration can seriously deteriorate the network performance by slowing down the system.

Example 1

Consider the following system of a single delayed differential equation

$$\frac{da}{dt}(t) = -a(t) + \tanh[2a(t - \tau)], \quad (1)$$

where the delay $\tau \geq 0$ is constant. This equation is used to describe a single neuron with delayed self-

excitatory positive-feedback connection. This equation has three equilibria: $a = a_- < 0$, $a = 0$, and $a = a_+ > 0$. If $\tau = 0$ then the equation is an ordinary differential equation without delay. In this case, if the initial condition $a(0) = a_0$ is strictly negative (positive), then the solution converges to a_- (a_+). So, all solutions but $a = 0$ converge to either a_- or a_+ , and the system is said to be bistable. The equilibrium point $a = 0$ is the boundary of the basin of attraction of a_- and a_+ . If $\tau > 0$, the initial condition is a continuous function $a_0: [-\tau, 0] \rightarrow \mathbb{R}$ that gives the history of the variable a up to time $-\tau$ (beyond $-\tau$ past cannot affect future). In this case the equation has a delay, and the space of initial conditions is infinite dimensional. It is possible to show (see Pakdaman et al. 1997b and references therein) that the system with delay is still bistable and most solutions converge to either equilibrium a_- or equilibrium a_+ . The difference to the case $\tau = 0$ is that the boundary of the basins of attraction of a_- and a_+ is an infinite dimensional set in the space of initial conditions. Any solution that starts at the basin boundary must oscillate forever either with a vanishing amplitude, as the solution tends to the unstable equilibrium $a = 0$, or with a finite amplitude, as the solution tends to an unstable periodic orbit which is in the basin boundary (see illustration in the Fig. 3). DITOs appear whenever the initial condition a_0 changes sign within the interval $[-\tau, 0]$ in a way that a_0 is close to but not in the basin boundary. These are the delay-induced transient oscillations (DITOs).

Example 2

The space of initial conditions of Eq. (1), $a_0: [-\tau, 0] \rightarrow \mathbb{R}$, changes with the delay parameter τ . When the goal is to analyze the dependence of the solution on the delay, it is convenient to fix the space of initial conditions to $a_0: [-1, 0] \rightarrow \mathbb{R}$ by rescaling time as $t = \tau s$. Eq. (1) becomes

$$\varepsilon \frac{da}{ds}(s) = -a(s) + \tanh[2a(s - 1)], \quad (2)$$

where $\varepsilon = 1/\tau > 0$. The time duration of the transient oscillations of Eq. (2) increases as ε decreases (τ increases). These oscillations last

Delay-Induced Transient Oscillation (DITO) and Metastable Behavior, Fig. 3 Schematic phase portrait representation of the boundary of the basins of attraction of the delayed self-excited neuron (Eq. 1). The gray surface represents the boundary separating the basins of attraction of the two stable equilibria $r_1 = a_-$ and $r_3 = a_+$. The boundary contains the unstable equilibrium $r_2 = 0$, together with an unstable closed orbit. Some solutions are transiently attracted to the oscillatory solutions on the boundary before approaching one of the stable equilibria $r_1 = a_-$, $r_3 = a_+$.

for times of order $\exp(c/\varepsilon)$, for some $c > 0$, as $\varepsilon \rightarrow 0$ (see Pakdaman et al. 1997b; Grotta-Ragazzo et al. 2010), so they are said to be *metastable*. In terms of the original time t , the metastable oscillatory pattern persists for a time of the order $\exp(c\tau)$. When ε is small enough, the metastable oscillatory pattern is close to a square-wave function (see Fig. 2, right panel).

DITO and the Boundary of the Basins of Attraction: Mathematical Tools

DITOs appear in various systems of delayed differential equations: one equation (Pakdaman et al. 1997b; Pakdaman and Malta 1998), two equations (Pakdaman et al. 1998b), and many equations (see Pakdaman et al. 1997a and entry ► “Time-Delayed Neural Networks: Stability and Oscillations”). In all these systems, almost all initial condition leads to a solution that converges to a stable equilibrium point. DITOs are generated by initial conditions close to the boundary of the basins of attraction, as in the

case of Eq. (1). So, the geometric understanding of DITO is related to the geometric understanding of the boundaries of the basins of attraction of the equilibria. The boundary of the basins of attraction of simple systems with a few stable equilibria may be very complicated. (For instance, for almost all initial condition, Newton’s method converges to one of the three roots of the complex polynomial $z^3 - 1 = 0$. The boundary of the basin of attraction of each attracting fixed point has the “Wada property,” namely, a point is in the boundary of one of the basins of attraction if, and only if, it is simultaneously in the other two basin boundaries.) So it is remarkable that it is possible to geometrically describe the boundary of the basin of attraction of delay differential equations (Pakdaman et al. 1997b, c, 1998a, 1999).

The mathematical property that allows for this description is the monotonicity of the semiflows generated by the equation. This property means that Eq. (2) (see Pakdaman et al. 1997b) is order preserving: if $a_0: [-1, 0] \rightarrow \mathbb{R}$ and $\hat{a}_0: [-1, 0] \rightarrow \mathbb{R}$ are two different continuous initial conditions such that $\hat{a}_0(\eta) \geq a_0(\eta)$ for $\eta \in [-1, 0]$, then for $s > 2$ the solutions $\hat{a}$ and a satisfy $\hat{a}_0(s + \eta) > a(s + \eta)$ for all $\eta \in [-1, 0]$. This is illustrated in Fig. 4. This order-preserving property implies that for a given continuous function $a_0: [-1, 0] \rightarrow \mathbb{R}$, the initial condition $a_0 + c$, where c is a real constant, generates a solution to Eq. (2) that converges to the equilibrium a_+ , if c is sufficiently large, or converges to a_- , if c is sufficiently small. Moreover, for a unique value of c , it converges neither to a_- nor to a_+ but remains oscillating in the boundary of the basin of attraction of a_+ and a_- . So the basin boundary is a subset of the set of initial conditions that is transversal to the one-dimensional subspace of constant functions in $[-1, 0]$. Similar ideas are used to describe the boundary of the basins of attraction for systems with two or more equations.

Are DITOs Always Metastable?

The answer is no. DITOs seem to appear very often in multi-stable delay equations, but the

Delay-Induced Transient Oscillation (DITO) and Metastable Behavior,

Fig. 4 Illustration of the order-preserving property

oscillations do not necessarily persist for a time t of the order of $\exp(c\tau^\beta)$, for some constants $c > 0$ and $\beta > 0$, as $\tau \rightarrow \infty$. The mathematical question of existence of metastable solutions is delicate as the following examples show. Consider a scalar equation of the form

$$\varepsilon \frac{da}{ds}(s) = -a(s) + f(a(s-1)). \quad (3)$$

Let us assume that

$f(a) = l$ if $a < 0$ (left value), $f(0) = 0$, $f(a) = r$ if $a > 0$, (right value).

If $l < 0$ and $r > 0$ (positive feedback), then the equation is bistable with two attracting equilibria $a = l$ and $a = r$. Since f is a piecewise constant, function an explicit computation (Grotta-Ragazzo et al. 1999) shows that DITOs are metastable if, and only if, $-l = r$. If $l > 0$ and $r < 0$ (negative feedback), then the equation has a single attracting periodic orbit, which attracts most initial conditions, with period $p(\varepsilon) > 2$ and exactly two sign changes within a period (a “slowly oscillating periodic orbit”). In this case, DITOs are transient oscillatory solutions with more than two sign changes in a time interval of length 2. In contrast to the positive-feedback case, in the negative-feedback case, metastable DITOs always exist regardless of the values of l and r . When f is a smooth function, the mathematical analysis of the existence of metastable oscillations for Eq. (3) is difficult. In Grotta-Ragazzo et al. (2010), using “transition layer equations” (Chow and Mallet-Paret 1983), in the positive-feedback case ($\frac{df}{da} > 0$), it was possible to show that odd symmetry of the positive-feedback f is a sufficient

condition for the existence of metastable oscillations. However, the oddness of positive-feedback f is not a necessary condition for metastability as there are positive-feedback functions f that are not odd but satisfy instead a condition formulated in terms of transition layer solutions, for which metastable oscillations occur. In the negative-feedback case ($\frac{df}{da} < 0$), metastable oscillations always exist (see Grotta-Ragazzo et al. 2010 for details), provided a “slowly oscillating periodic orbit” exists.

Metastable oscillations were detected not only in scalar equations but also in systems (Pakdaman et al. 1997a, b, 1998b). In all these works, the existence of metastable oscillations was shown by both numerical investigation and theoretical analysis using symmetries of the equations. For scalar equations or systems, if f is smooth or not, the short-time stability of metastable oscillatory patterns is a consequence of the behavior of the system in the singular limit $\varepsilon = 0$ (the analysis of the singular limit is a classical idea present in several previous results, for instance, Chow and Mallet-Paret 1983; Ikeda and Matsumoto 1987; Sharkovsky et al. 1993).

In physics, metastable behavior is mostly related to phase transitions as some parameter (for instance, temperature) crosses some threshold value (Fusco and Hale 1989). In a bistable system, the phase transition value separates parameter regions where either one of the stable states dominates. In multi-stable complex networks modeled by differential equations with delay, the analysis of transient time duration may be an important and practical tool to detect important global changes in the system due to variation of a parameter that is not the delay. For instance, for the piecewise

constant f with fixed $l < 0$ and varying $r > 0$, metastable oscillations occur at $r = -l$, where the system has a reflection symmetry that interchanges the two equilibria. As the analysis in the positive feedback shows (Grotta-Ragazzo et al. 2010), at a phase transition threshold, the system does not have to exhibit an explicit symmetry like the oddness of the function f .

Conclusion

DITOs seem to appear quite often in multi-stable systems of delayed differential equations, for constant delay, and also for state-dependent delay (Pellegrin et al. 2014). The transient oscillations occur for initial conditions close to the boundary of the basins of attraction. The time duration of transient oscillations may be very long and, depending on the system, may increase exponentially with increasing delay. In this case DITOs could be misidentified as stable oscillations. Metastable patterns may appear at a particular value of a parameter of the system, and this can be an indication of a dynamical “phase transition” at that value.

Synonyms

Slow oscillation; Slow-wave oscillation (SWO)

Definition

A high amplitude brain rhythm with frequency between 1 and 4 Hz.

Detailed Description

History

The term “delta” was first introduced by Walter in 1936 to describe frequencies below the alpha (9–11 Hz) band while attempting to diagnose tumors using EEG signatures (Walter 1936). He subsequently, with Berger, subdivided this band to include theta rhythms (between 4 and 8 Hz). Since then the presentation of delta rhythms has been shown to be variable in frequency and amplitude during sleep (Church 1975), and some observers subdivide delta further into delta1 (1–2 Hz) and delta2 (3–4 Hz); this may have some mechanistic validity given the different potential origins of the rhythm (see below, Weiss and Rappelsberger 2000).

Association with Brain State

Delta rhythms (1–4 Hz) are predominantly associated with deep sleep (stage N3). These sleep stages are manifest most strongly during the first few hours of sleep in humans, occurring iteratively in epochs of ca. 0.5–1.0 h, with decreasing power as sleep progresses (Campbell 2009). They have been linked to the consolidation of memories of consciously experienced events (Huber et al. 2004). However, it currently remains unclear how such memory consolidation may take place. The correlation with deep sleep is reinforced with observations of very large increases in delta rhythms following sleep deprivation and an association with narcolepsy.

Delta rhythms are also associated with certain forms of cognition during wakefulness. They are manifest during the processing of repetitive auditory sensory information (Lakatos et al. 2008), being precisely phase reset by entrainment to such inputs. This results in response gain enhancement and reaction time improves (Lakatos et al. 2008). Such a process is seen predominantly when there is a pattern of sensory input to entrain to. Without such predictable input, the lower frequency delta “carrier wave” becomes detrimental to cortical function and is actively suppressed in favor of a state of near-continuous

vigilance manifest as continuous high-frequency rhythms (Schroeder and Lakatos 2009).

Function

Little is known with certainty about what delta rhythms do in the brain. In general, slow-wave sleep is associated with consolidation of declarative memory – suggesting a role in modifying synaptic plastic changes induced during wakefulness by sensory input. This has led to the “synaptic rescaling” hypothesis – the restoration of a mean baseline of synaptic weights in the cortex (Tononi and Cirelli 2003, 2006). The type of plasticity seen during deep sleep appears to be dominated by long-term depression. Dopaminergic neuromodulation is very low during deep sleep, and, specifically, D1 receptor activation impairs long-term depression and enhances spike timing-dependent long-term potentiation (Xu and Yao 2010). Computational models predict that as delta rhythms decline during sleep, so does overall cortical synaptic strength (Riedner et al. 2007), and, experimentally, GluR1 receptor phosphorylation levels are potentiated during wakefulness and depressed after sleep (Vyazovskiy et al. 2008). From a synaptic dynamic point of view, activity in the delta frequency band in general facilitates depression (Staubli and Lynch 1990).

If delta rhythms do chaperone a synaptic depression process, which exact cortical representations are being attenuated? Sleep-associated slow rhythms in general have been proposed to be temporally discrete (hundreds of ms) fragments of wakefulness (Destexhe et al. 2007). Thus it is perhaps not surprising that brief, iterative epochs of sensory-/memory-associated cortical representations are somehow operated upon during delta (Peyrache et al. 2009; Riedner et al. 2007). By “cortical representation,” we mean here “defined sets of synapses and the neurons they interconnect.” Studies on delta rhythms generated experimentally in local circuits of association cortex have shown an iterative cycle of reciprocal interactions between superficial and deep cortical laminae (Carracedo et al. 2013). This type of switching between descending and ascending interlaminar interactions has been seen during

wake states on a slower timescale and more persistently during memory tasks: Coding of sensory inputs is associated with descending interlaminar communication, whereas the subsequent memory component of the task involves a switch to ascending interactions (Takeuchi et al. 2011). In addition, this pattern of activity closely matches the “Helmholtz machine” proposed by Hinton and colleagues as a general format for unsupervised learning (Hinton and Zemel 1994; Hinton et al. 1995). The mechanistic key to any selectivity in changing synaptic weights comes from the interaction of delta rhythms with theta oscillations. *More active neurons* generate outputs at the delta-nested theta frequency, which promotes or preserves synaptic weights (Larson et al. 1986), whereas *weaker activated* neurons fire only at the synaptic depression inducing delta frequency.

Mechanism

When considering experimental evidence for mechanisms underlying delta rhythms, it is important to clearly define the frequency band. Oscillations faster than 4 Hz in the neocortex are mechanistically distinct (from delta) when they coexist with such delta rhythms – the faster oscillations involve a different population of layer 5 pyramidal neurons from those generating the delta rhythm (Carracedo et al. 2013). Frequencies lower than 1 Hz are also seen with delta rhythms during very deep sleep but, again, appear to have different mechanisms (Steriade et al. 1990). In particular the dependence of very slow “up-/down-state” oscillations has been shown to be exquisitely sensitive to balance between fast synaptic excitation and inhibition, while delta rhythms are more robust in this respect (cf Carracedo et al. 2013 with Haider et al. 2006). This entry will consider delta rhythm mechanisms only. It will focus on a brief description of what is known about the thalamic and neocortical generators separately, though both clearly interact to produce the rich dynamic signatures associated with noninvasive recordings of in vivo brain function during slow-wave oscillations (Crunelli and Hughes 2010).

Thalamic Generator

A thalamic generator of delta (1–4 Hz), modified by sensory input, is seen in the thalamus (Amzica et al. 1992). This delta activity persists after disconnection of the thalamus from the cortex (Steriade et al. 1987) and can be seen in individual thalamocortical cells in a manner dependent on membrane potential (McCormick and Pape 1990). These authors showed a mechanism involving behavior of intrinsic membrane conductances (I_h and I_T , respectively, the anomalous rectifier and low-threshold, T-type, calcium conductance). Specifically, a window current generated by T-type calcium channels, formed by the overlap at around -60 mV between their steady-state activation and inactivation behaviors, has been well characterized (Pirchio et al. 1997; Hughes et al. 1999, 2002). Small perturbations in membrane potential around this window generate large signal amplifications and the rhythmic behavior typical of thalamic delta rhythms (Williams et al. 1994). The conditions in which expression of this intrinsic delta behavior is favored in vitro match the neuromodulatory state of the in vivo brain during deep sleep. Cholinergic and monoaminergic tone are very low during deep sleep, abolishing a tonic depolarized state in thalamocortical neurons (McCormick and Pape 1990) and facilitating activation of the window current.

Neocortical Generator

Some forms of delta rhythm have characteristics, suggesting a purely cortical origin (Amzica and Steriade 1998; Fell et al. 2002). During deep sleep, cortical delta rhythms can be generated locally (Vassalli and Dijk 2009), sometimes having dynamic properties consistent with discrete cortical region specificity (Vyazovskiy et al. 2011). In general the expression of delta in cortex shows strong nonuniformity – favoring the frontal-parietal axis (Ioannides et al. 2009).

Current source density measurements during sleep in experimental animals and humans reveal a strong source in superficial layers, suggesting that any synaptic drive underlying delta rhythms was located in these layers (Csercsa et al. 2010).

In contrast, targeted activation of deep layer pyramids strongly modulated slow-wave sleep rhythms, whereas targeted activation of superficial neurons did not (Beltramo et al. 2013). A potential resolution to this dichotomy came from in vitro models of local delta rhythms that showed a critical role for intrinsically bursting neurons in layer 5 of the parietal cortex (Carracedo et al. 2013). These neurons have cell bodies in upper layer 5 but also have tufted distal apical dendrites extending up through layers 1–3. Pharmacological manipulation of this model demonstrated a mechanism whereby interplay between slow GABA_B receptor-mediated inhibition and NMDA receptor-dependent synaptic excitation, and gap junctional excitation, was vital to delta generation. Intrinsically bursting neurons have high concentrations of these synaptic receptor subtypes out on their distal dendrites suggesting that whereas the synaptic connections that underlie the rhythm as an emergent property of local networks are located mainly in dendrites in superficial layers, the intense burst outputs of these neurons during delta arise from the somata of these cells in deep layers.

This experimental prediction for the core delta mechanism model is supported by observations showing that reduced gap junction conductance, or blockade of NMDA receptors, reduces slow-wave sleep and layer 5 neuron bursting (Armstrong-James and Fox 1988; Franco-Pérez and Paz 2009). In addition, generation of intense bursts from interneurons appeared to underlie the slow GABA_B receptor-mediated IPSP separating the active phase of each delta period, perhaps through volume conduction of GABA overspill from intensely active synapses and/or neurogliaform neuronal output (Oláh et al. 2009). However, a remarkable division of labor appears to exist in layer 5. While *intrinsically bursting* neurons participate in circuits generating delta, their outputs nest a theta generator centered around layer 5 *regular spiking* neurons. It is this nested theta output that provides the substrate for at least one set of “weights” in the Helmholtz analogy – those dictating the degree of reciprocal interlaminar interaction seen on each delta period.

Models

Thalamic Models

The intrinsic delta generator in thalamocortical neurons has been modeled extensively based on the interplay between a hyperpolarization-activated nonspecific cation current (I_h) and the transient low-threshold calcium current (I_T) (see Tóth and Crunelli 1992). In addition most model neurons possess a leak conductance and fast currents underlying sodium spikes (I_{Na} and $I_{K(DR)}$, Traub et al. 1991). In single-compartment models the steady-state values for activation and inactivation of I_T and I_h were critical in generating both the occurrence and frequency of delta rhythms and the transition from slow delta bursting to fast, continuous firing (Williams et al. 1997, Fig. 1). Using multicompartment models capturing the dendritic structure of thalamocortical cells, it has been shown that a distal dendritic location of these two currents was optimal for delta generation (Lytton et al. 1996) – a prediction with interesting consequences when considering the proximal vs. distal location of inputs to these neurons from ascending sensory streams and feedback corticothalamic neurons.

Further development of these thalamocortical models included interaction with GABAergic

neurons in thalamic reticular neurons. Neurons in the nucleus reticularis also show burst behavior at hyperpolarized membrane potentials with dependence on I_T . Coupling such neurons with model GABAergic synapses generated robust oscillations in the spindle frequency range (7–14 Hz) (Destexhe et al. 1998) and provides a compelling basic structure, when coupled to thalamocortical neurons, for interaction between spindling and delta rhythms seen in vivo.

Neocortical Models

In contrast to the dominance of intrinsic single-cell conductance interactions for the thalamic generator, a combination of (a) compartment-specific conductance expression and (b) the manifestation of the neocortical delta rhythm as an emergent property of local networks requires a more complex model structure to capture biological realism. The cortical column model of Traub et al. (2005) was modified to generate the delta computational model in Carracedo et al. 2013. The model predicted the experimental derivation of the core delta rhythm circuit with high fidelity in a circuit consisting of 2000 layer 5 intrinsically bursting neurons, coupled via NMDA receptors and gap junctions, driving GABA_B receptor-mediated feedback dendritic

Delta Rhythms: Models and Physiology, Fig. 1 Comparison of single-cell electrophysiology with computational model of thalamic delta oscillations. (a) and (b) show the upper and lower limits of existence of the

window current-generated delta rhythm in thalamocortical cells (experiment) and computational model. Frequency ranged from ca. 0.6–1.6 Hz. Scale bars 20 mV, 4 s. (Adapted from Williams et al. 1997, Fig. 7)

inhibition through mixed glutamatergic excitation of “neurogliaform” interneurons (fast spiking interneurons modified to be delayed spiking via somatodendritic “A”-type potassium conductance).

In this manner, the model reproduced dominant, delta-locked spike outputs in intrinsically bursting and neurogliaform cells. The behavior was initiated by predominantly NMDA receptor-mediated recurrent excitatory connections between intrinsically bursting cells and terminated by a combination of the strong intrinsic afterhyperpolarization (SK-type potassium channel-mediated) in this neuron subtype and a phasic GABA_B receptor-mediated slow inhibitory postsynaptic potential. It also suggested the layer 5 nested theta generator was mediated by a combination of regular spiking layer 5 neuron intrinsic properties and their appropriately weighted synaptic inputs (Fig. 2).

Combined Models

Currently no model has been published combining the biophysical detail of both the cortical and thalamic delta generators highlighted above. However, higher-level simulations using integrate and fire neurons have been generated and used to understand the emergence of behavior typical of slow-wave sleep, again implicating low-threshold bursting neuron in controlling the global thalamocortical network state (Destexhe 2009). In general such models reveal much reciprocity in thalamocortical interaction: Cortical projections to thalamus play a vital role in stabilizing thalamic output, as seen in experiment (Contreras et al. 1996), and conversely thalamic projections to the cortex are vital in controlling neuronal response state (Bazhenov et al. 2002). While increasingly biophysically accurate models are being generated, similar basic principles become apparent:

Delta Rhythms: Models and Physiology,

Fig. 2 Comparison of electrophysiology with network computational model of neocortical delta oscillations. Extracts of field (a) and single neuron subtype behavior in a columnar model of local circuit interactions. The ca. 2 Hz rhythm in layer 5 field recordings was accompanied by intense spike bursting in intrinsically bursting (IB, layer 5 pyramids (b)) cells, fast spike bursts in basket cells (FS1), and intense spike bursts and theta-frequency single spiking in model neurogliaform cells (FS2, c). In contrast layer 5 regular spiking cells (RS) generated packets of theta-frequency single spike outputs phase locked to the delta rhythm (d). Scale bars 30 mV, 600 ms. (Adapted for Carracedo et al. 2013)

The detailed biophysical thalamocortical model of Hill and Tononi (2005) reiterated the importance of hyperpolarization of neurons (in their case via an increase in potassium leak conductance) in stabilizing a c.2 Hz delta rhythm. In addition, in the cortex and thalamus, a vital role for I_h was also evident.

Definition

Dendritic computations refer to the ability of individual dendritic branches to perform elementary computations on incoming signals. These computations include addition, subtraction, multiplication, and division and can also take the form of logical operations (e.g., AND, OR, XOR). In this

chapter, we discuss evidence regarding the type of computations that have been observed in dendritic branches of multiple neuron types as well as the impact of these computations on the function of neural cells and circuits.

Detailed Description

Dendrites are elaborate processes that extend from the cell body of neurons and form the locus of synaptic communication between cells. The biophysical mechanisms that reside in dendrites allow them to locally integrate synaptic inputs in a linear and/or nonlinear manner enabling them to perform different types of computations (London and Häusser 2005; Silver 2010). In the following paragraphs, we discuss several examples of dendritic integration focusing primarily on pyramidal neurons, as these cells comprise the main processing class in the brain (Spruston 2008).

Factors That Influence Dendritic Integration

The ways in which incoming inputs are combined within dendritic branches depend mainly on two factors: (a) the morphology of the dendritic tree and (b) the repertoire of local ionic conductances. Dendritic morphology together with ionic mechanisms whose conductance does not depend on membrane voltage shapes the “passive” properties of neurons, while voltage-dependent mechanisms contribute to the “active” properties of neurons. The following sections discuss examples of how *passive* and *active* mechanisms shape dendritic properties and in turn the output of the neuron.

Passive Properties

The traditional view of dendritic processing considered dendrites as passive devices whose primary function is to transmit signals towards the soma. The extended morphology of the dendritic tree often seen in multiple neuron types was

simply considered as a means of increasing the surface area for receiving synaptic inputs. This simplified view of dendrites resulted in their omission from early neuronal models, whereby all processing was done at the cell body. Specifically, single neurons were treated as thresholded summation devices that generated an axon potential when the additive combination of incoming signals reached a certain threshold (McCulloch and Pitts 1943), completely disregarding the function of dendrites.

This notion of dendrites as conduction wires led to the formulation of “passive cable theory” which describes how electrical signals travel from their point of origin in a particular dendrite towards other parts of the neuron. A few years later, applications of the cable theory revealed that the complex geometry of dendrites in combination with their passive properties enables neurons to integrate their inputs in highly nonlinear ways. For example, when a postsynaptic potential propagates through a passive dendrite towards its integration site (soma or axon), its amplitude is attenuated in a distance-dependent manner. This effect was first described theoretically by Wilfrid Rall back in 1967 (Rall 1967), whose work revealed that passive dendrites act as low-pass filters. The diameter of dendritic branches affects the filtering of synaptic inputs for two reasons: (a) Distal dendrites are usually thinner compared to proximal ones, and as a result, synaptic potentials that travel towards the soma are reduced in amplitude (Rinzel and Rall 1974; Zador et al. 1995). This attenuation can be more than 100-fold, in pyramidal neurons (Stuart and Spruston 1998) or in cerebellar Purkinje cells (Vetter et al. 2001), and it appears to be similar for the apical and basal trees, at least in layer V pyramidal neurons (Williams and Stuart 2002; Nevian et al. 2007). (b) A smaller dendritic diameter results in larger input resistance which in turn leads to larger local EPSPs. Membrane capacitance is also smaller due the reduced membrane area, inducing faster local depolarizations in distal dendrites (Rinzel and Rall 1974; Agmon-Snir and Segev 1993).

Due to the abovementioned anatomical properties, summation of multiple excitatory synaptic

inputs within passive dendrites depends on the degree of their spatial and temporal isolation: When inputs are spatially clustered or synchronously activated, they summate sublinearly, as a consequence of the reduction in the ionic driving force. However, this conclusion is reversed when taking into account the presence of voltage-dependent (active) conductances that greatly influence local responses and counteract attenuating effects.

Active Properties

Over the last decade, advances in technology led to the discovery of an array of voltage-dependent ion channels with different densities and biophysical properties that lie along the axo-somato-dendritic axis (Spruston 2008). These findings revealed the key role of dendritic branches in shaping synaptic integration locally and in turn the response of the neuron. Dendrites are enriched with a variety of voltage-dependent channels, whose conductance and distribution differ among neuronal types, dendritic layers (e.g., apical vs. basal dendrites), as well as with distance from the cell body. Therefore, the integration of synaptic inputs does not only depend on the specific morphological features and passive properties of the dendritic tree but also on the expression profile and kinetics of the various active conductances.

The toolkit of active dendritic mechanisms includes a variety of channel types, such as Na^+ , Ca^{2+} , K^+ , and h channels and NMDA receptors. In general, Na^+ and Ca^{2+} channels are considered as boosters of postsynaptic potentials, whereas both K^+ and h channels are more likely to dampen dendritic excitability and contribute to the control of action potential frequency or act as pacemaker currents, respectively (Migliore and Shepherd 2002; Larkum and Nevian 2008; Spruston 2008). Importantly, various ionic conductances in the dendrites, such as sodium (Stuart and Sakmann 1994), calcium (Yuste et al. 1994), NMDA (Schiller et al. 2000), or a combination of the above (Wei et al. 2001; Ariav et al. 2003), have been shown to facilitate the back- or forward-propagation of dendritic spikes, allow the supralinear summation of synaptic inputs as

shown in Fig. 1a, b (Poirazi et al. 2003a, b; Polsky et al. 2004; Losonczy and Magee 2006), and enhance LTP induction (Magee and Johnston 1997; Remy and Spruston 2007). In particular, NMDA receptors when sufficiently activated can lead to the generation of dendritic regenerative events termed NMDA spikes.

Those spikes are characterized by larger local amplitude and duration, compared to the briefer Na^+ spikes, but smaller amplitude compared to Ca^{2+} spikes. NMDA spikes are highly localized events, confined to thin dendritic branches. For these reasons, NMDA spikes are considered an attractive dendritic mechanism for the detection of incoming signals that arrive at close temporal and/or spatial proximity (Ariav et al. 2003; Losonczy and Magee 2006). Interestingly, recent work has assigned new roles to NMDA spike generation: (a) to extend the temporal window for supralinear integration in CA1 pyramidal neuron dendrites in response to bursty signals (Gomez et al. 2011) and (b) to serve as a mechanism for the detection of “preferred” sensory signals, namely, signals that will induce persistent activity in a single-layer V PFC pyramidal neuron (Sidiropoulou and Poirazi 2012). Importantly, the majority of the excitatory glutamatergic inputs in layer V pyramidal neurons is received by their basal, oblique, and apical tuft dendrites that can give rise to regenerative NMDA events (Antic et al. 2010).

Although such regenerative events can be confined to their dendritic site of origin (Schiller et al. 2000; Wei et al. 2001), physiologically relevant situations such as large, suprathreshold synaptic stimuli in the distal dendrites or the co-activation of several branches allow these spikes to act globally and modulate neuronal output (Larkum et al. 2001). Thus, dendritic events emerge as key players in shaping neuronal responses.

Dendritic Morphology

While extensive experimental and theoretical work has characterized the arithmetic of synaptic summation in pyramidal neurons, the role of dendritic morphology in this process remains poorly understood. Electrophysiological characterization with current injection has shown that neurons with

Dendritic Computation, Fig. 1 Nonlinear dendritic computations. **(a)** Summation of paired, single-pulse inputs in the apical dendrites of a CA1 pyramidal model cell. Simulations predict a sigmoidal modulation of combined excitatory postsynaptic potentials (EPSPs) within a branch (red symbols) and a linear summation of EPSPs between branches (green symbols). Red curves correspond to within-branch data for dendrites at 92 μm (short dashes), 232 μm (solid), and 301 μm (long dashes) from the soma. Due to differences in local compared with somatic responses, axis values for the red curves are scaled up by a factor of 10. **(b)** Experimental verification of predicted summation rules in basal dendrites of a layer V pyramidal

neuron as reported in Polsky et al. (2004). Single-pulse stimulation of synapses in different branches results in linear summation at the cell body (green squares). When γ -aminobutyric acid (GABA)ergic inhibition is blocked, the summation of within-branch EPSPs is modulated by a sigmoidal nonlinearity (all other symbols). **(c)** Schematic representation of a pyramidal neuron as a two-layer neural network. Radial oblique dendrites provide the first layer of the network, each performing individually thresholded computations as shown in **(a)** and **(b)**. The outputs of this layer feed into the cell body, which constitutes the second layer of the network model (Reproduced with permission from Sidiropoulou et al. (2006))

a more complicated morphology (in terms of larger and more elaborate dendritic trees, more branches, extensive bifurcations, and more spines) display bursting firing patterns, whereas neurons with simpler morphologies tend to fire tonic spikes (Bilkey and Schwartzkroin 1990; Chagnac-Amitai et al. 1990; Yang et al. 1996).

Simulations of reconstructed neurons are in accordance with the *in vitro* studies (Mainen and Sejnowski 1996; Sheasby and Fohlmeister 1999; Krichmar et al. 2002) and further propose that dendritic trees with asymmetric branch connections are associated with bursting (van Elburg and van Ooyen 2010).

The branching pattern of the dendritic tree also influences both the forward and the back-propagation of signals (Vetter et al. 2001) while at the same time shaping coincidence detection (Schaefer et al. 2003). Even the area of the bifurcation tapering membrane surrounding a branch point can determine neuronal excitability, through its effects on the generation, propagation, and timing of dendritic spikes (Ferrante et al. 2013). Taken together, the elaborate morphology of the dendritic tree seems to play a critical role in shaping dendritic as well as neuronal responses.

Importance and Functional Implications of Dendritic Computations

The various active properties of dendrites expand the computational capabilities of various neuron types and add spatiotemporal specificity to their functional output (Stuart et al. 2008, 2010; Silver 2010). In pyramidal neurons, synaptic inputs are integrated linearly when they are located on different dendritic branches and sigmoidally when located within the same dendrite (Poirazi et al. 2003a; Poirazi et al. 2003b; Polsky et al. 2004; Losonczy and Magee 2006), but they could also be integrated sublinearly, depending on the spatial distribution of incoming signals (Oviedo and Reyes 2012). In CA1 pyramidal neurons, dendrites produce two distinct modes of integration: Asynchronous or spatially distributed synaptic inputs are integrated linearly, while synchronous and/or clustered inputs are integrated in a sigmoidal manner (Cash and Yuste 1999; Gasparini and Magee 2006). These phenomena are mediated by the generation of dendritic spikes that are locally confined.

The combination of a complex dendritic morphology with a location-specific distribution of ionic mechanisms results in the formation of distinct dendritic subunits which can integrate inputs in a quasi-independent manner (Poirazi et al. 2003a, b; Polsky et al. 2004; Losonczy and Magee 2006), thus enabling the cell to integrate inputs like a two-layer neural network. This ability to integrate inputs like a two-layer neural

network, graphically illustrated in Fig. 1c, boosts the computational capacity of the neuron by at least an order of magnitude compared to that of a thresholding point neuron (Poirazi and Mel 2001). Recent experimental evidence shows that the distribution of synapses both along the somatodendritic axis and along the oblique branches in CA1 pyramidal neurons favors a two-stage integration model (Katz et al. 2009).

At a smaller scale, single dendrites of layer II/III and layer V pyramidal neurons exhibit non-uniform synaptic integration modes along their length. Synaptic inputs in the distal end of the dendrite summate sigmoidally with a low threshold for dendritic spike generation, while inputs to the proximal end of the same dendrite summate linearly and exhibit a higher threshold for dendritic spikes (Major et al. 2008; Branco and Häusser 2011). These and previous data indicate that the spatial arrangement of synaptic inputs within dendritic branches greatly influences local responses by differentially engaging local conductances (Larkum and Nevian 2008). For example, the co-activation of nearby synapses, also termed “synaptic clustering,” leads to signal amplification via the induction of dendritic spikes, resulting in a much larger somatic response than the one obtained when the same number of synapses is stimulated in a distributed manner. As dendritic depolarization and dendritic spikes can have a strong effect on LTP induction, clustered synapses are also more likely to undergo stronger potentiation than diffusely activated inputs (Hardie and Spruston 2009).

Overall, these findings show that dendritic arithmetic obeys complex rules that are often not only brain region but also branch-type specific. This ability of dendrites to perform complex local computations has led to the proposal that dendritic branches (as opposed to single synapses or whole neurons) should be considered as the lowest-level processing unit of the nervous system (Branco and Häusser 2010). If proven, this hypothesis will change our current view of information processing and storage in the brain and will open new avenues for experimental investigations regarding the cellular substrate of learning and memory.

Dendritic Spines

William R. Holmes

Department of Biological Sciences, Ohio University, Athens, OH, USA

Definition

Many types of neurons receive synaptic inputs on dendritic spines which are short protrusions of membrane composed of a bulbous “head” connected to the dendrite by a thin “stem” or “neck” (Yuste 2010). Although spines are typically small in size, they occur in high densities along dendrites and may compose 40–60% of the total dendritic surface area. There are two straightforward methods for including spines in computational models of neurons without representing every spine explicitly.

Detailed Description

Spines are widely regarded to serve a biochemical function by providing an isolated compartment where highly localized calcium signals and subsequent reactions can occur. An electrical function was initially proposed by Rall who showed that the steady-state attenuation of a signal from the spine head to the dendrite could be expressed as $V_{SH}/V_{BI} = 1 + R_{SS}/R_{BI}$, where V_{SH} and V_{BI} are the voltages at the spine head and dendrite, respectively; R_{SS} is the spine stem resistance; and R_{BI} is the input resistance at the dendrite. Rall suggested that changes in spine stem diameter might be important for plasticity because of its effect on R_{SS} , but studies searching for such changes produced mixed results. Others have suggested that if voltage-dependent conductances are present on spines, then spines might amplify inputs and could otherwise increase the computational possibilities of the cell. Many of the more interesting possibilities suggested by theoretical studies require a large R_{SS} , but whether or not R_{SS} is sufficiently large has been controversial.

Dendritic Operations

► Dendritic Computation

Because the proportion of membrane area occupied by spines can be large, single-neuron models that ignore spines are bound to produce erroneous results. There are two straightforward methods for including spines in models without coding each and every spine, as long as these implicitly included spines do not receive synaptic input. First, if dendritic and spine membranes are assumed to have the same specific membrane resistance and capacitance, R_m and C_m , spines can be implicitly included in a model by increasing C_m and reducing R_m according to the proportion of total membrane area contributed by spines. We call this the R_m - C_m method. For example, if spines increase the membrane area of a dendrite by 33%, then spines can be implicitly modeled by multiplying the dendrite C_m by 1.33 and dividing dendritic R_m by 1.33. Alternatively, one can keep R_m and C_m constant but increase length and diameter in such a way as to keep intracellular resistance constant (i.e., keep length/diameter² constant). We call this the l-d method. For example, if spines increase membrane area by 33%, let $F = 1.33$ and multiply length by $F^{2/3}$ and diameter by $F^{1/3}$.

These two methods for including spines in models implicitly provide identical results with passive models, but they make very different assumptions when voltage-dependent conductances are present. The first method, where R_m and C_m are changed, assumes that spines have passive membrane, while the second method, where length and diameter are changed, assumes that the spines have the same densities of voltage-dependent conductances as the dendrite. The cell should have a lower input resistance with the second method but should also respond more nonlinearly with voltage perturbations. Needless to say, results may be very different.

Nevertheless, it is straightforward to modify either method to include spines possessing different densities of voltage-dependent conductances than present on the dendrite. With the first method, one should change dendritic R_m and C_m as described above but also modify the maximum conductance density (g-bar) for each conductance

by $\bar{g}_{d-new} = (\bar{g}_{d-old}A_d + \bar{g}_{spine}A_s)/A_d$ where A_d is the membrane area of the dendritic segment and A_s is the membrane area of all spines on that segment. With the second method, one should modify the maximum conductance density for every conductance on each dendrite by $\bar{g}_{d-new} = (\bar{g}_{d-old}A_d + \bar{g}_{spine}A_s)/(A_d + A_s)$ and then change length and diameter of the dendrite as described above. These expressions assume spine head and neck have the same channel densities. If this is not true, one could calculate an equivalent $\bar{g}_{spine}$ to use.

These methods are easily incorporated into single-neuron simulators such as NEURON or GENESIS and work well for voltage-dependent conductances with fixed reversal potentials. However, these methods are subject to error when calcium and calcium-dependent conductances are present and particularly so if these conductances have different densities in spines and dendrites. Calcium accumulation and removal can be different in spines and dendrites, and different intracellular calcium concentrations will affect the calcium Nernst potential and activation of calcium-dependent conductances differently. The R_m - C_m method is preferred if dendrites have calcium conductances and spines do not. The l-d method is preferred if calcium conductances are on both dendrites and spines, but activation of calcium-dependent potassium conductances in spines remains problematic. It is possible to compensate for these types of errors by adjusting calcium pool parameters or by considering spine calcium and calcium-dependent conductances as separate conductances with their own parameters when conductances are merged into dendrites. These errors are not likely to be significant in short-time simulations but can be seen to accumulate over longer time periods.

Synonyms

Baer-Rinzel (BR) continuum model; Continuum spine model; Continuum spine theory; Continuum theory for active spines

Definition

The continuum theory for dendritic spines, developed by Baer and Rinzel (1991), is an extension of classical cable theory for which the distribution of spines is treated as a continuum. The theory applies when the interspine distance is much less than the length scale of the dendrite, for example, when the dendrite is populated by a large number of spines. The formulation maintains the basic feature that there is no direct coupling between neighboring spines; voltage spread along dendrites is the only way for spines to interact. With the continuum theory, different spine morphologies, multiple populations of spines, and distributed physiological properties are represented explicitly and compactly by relatively few differential equations. The theory is general so that idealized or realistic kinetic models may be adapted.

Detailed Description

Classical cable theory has provided valuable insights into structure-function relationships and guidance in the design of experiments. Perhaps the best example is Rall and Shepherd's electrotonic model of the olfactory bulb, which predicted the existence of functional dendrodendritic synapses (Rall and Shepherd 1968). Cable equations have been used successfully to study tapered nerves and extensively branched dendritic trees

(Jack et al. 1975; Rall 1977), as well as cables with nonuniform electrical parameters such as specific membrane resistivity (Holmes and Woody 1989).

In the 1970s and 1980s, Rall, Rinzel, Miller, and Segev spearheaded efforts that accelerated the theoretical investigation into the function of dendritic spines (Rall and Rinzel 1971a, b; Miller et al. 1985; Shepherd et al. 1985; Rall and Segev 1987; Segev and Rall 1988). Dendritic spines are small knoblike evaginations of the dendritic surface (see Fig. 1a, b), and a single neuron may have 10^5 spines. These large numbers of spines present a challenge for computational studies, particularly when using compartmental modeling. To address this, Baer and Rinzel (1991) formulated an extension of classical cable theory to model cables with large spine densities. They treated the distribution of spines as a continuum (see Fig. 1). This allowed a single cable with hundreds or thousands of spines to be modeled with just a few differential equations. Baer and Rinzel's model is

$$\tau_m \frac{\partial V_d}{\partial t} = \frac{\partial^2 V_d}{\partial X^2} - V_d + R_\infty \bar{n}_i I_{ss} \quad (1)$$

$$C_{sh} \frac{\partial V_{sh}}{\partial t} = -I_{ion} - I_{syn} - I_{ss}, \quad (2)$$

where

$$I_{ss} = \frac{V_{sh} - V_d}{R_{ss}}. \quad (3)$$

Here, V_{sh} and V_d are, respectively, the membrane potential in the spine head and the dendritic base (or shaft). Equation 1 is the cable equation in terms of dimensionless (electrotonic) length X (computed for the passive cable without spines), τ_m is the membrane time constant, and R_∞ is the input resistance for a semi-infinite passive cable with circular cross section. The spine density $\bar{n}$ expresses the number of spines per unit electrotonic length. The spine stem current is denoted by I_{ss} and represents the $I \cdot R$ voltage drop across the spine stem resistance R_{ss} , as expressed in Eq. 3. The spine head is modeled in Eq. 2 as an

Dendritic Spines: Continuum Theory, Fig. 1 Continuum of dendritic spines. (a) Cortical pyramidal cells (Modified from Berkley 1897). (b) A schematic magnification from (a) shows the dendrite (cylinder) studded with spines. (c) If there are many spines, the dendritic electrical response can be approximated by

considering a continuum of spines (stippled envelope). Although spines are treated mathematically as a continuum, the model is constructed so that spines interact only through spread of dendritic potential. (From Baer and Rinzel 1991; Fig. 1)

isopotential compartment with surface area A_{sh} (μm^2) and specific membrane capacitance C_m ($\mu\text{F}/\text{cm}^2$); individual spines have a capacitance of $C_{sh} = A_{sh} C_m$ (μF). Equation 2 describes the membrane potential in a single spine obtained from a current balance relation for the capacitive, ionic, spine stem, and synaptic currents.

The primary focus of Baer and Rinzel's study was on threshold properties, e.g., minimum number of synaptically activated spines, or minimal density of spines, for the initiation and spread of activity. They found that propagation was precluded for spine stem resistance (R_{ss}) either too large or too small (Fig. 2). Moreover, even if R_{ss} was in a suitable range for the local generation of an action potential (resulting from local synaptic

excitatory input), the range was shown to be not suitable to initiate a chain reaction of spine firings along the dendrite; success or failure of impulse propagation depends on an even narrower range of R_{ss} values. Also demonstrated was that appropriate clustering of spines can enhance synaptic amplification and spread of activity (Fig. 3).

The Baer-Rinzel model led to some new and important insights into the electrical interplay between passive and excitable membranes. For example, regions of decreased conduction load (e.g., near sealed ends of nerves) have a higher safety factor and therefore facilitate attenuating waves and further enhance waves that are successfully propagating. In regions of increased

Dendritic Spines: Continuum Theory, Fig. 2 Propagation failure for spine stem resistance too large or too small. A dendrite of electrotonic length 3 has 60 uniformly distributed excitable spines. Four spines are synaptically activated near $X = 0$ using an alpha function stimulation. Electrode recordings in the spine head and dendrite are simulated at $X = 0$ and $X = 2$. (a) Voltage transients in the head indicate propagation failure when the spine stem resistance is too low (short-dashed curves) because dendritic loading effectively raises the threshold for a local action potential out of range for the given input.

Propagation also fails when the stem resistance is too high (long-dashed curves) because large stem resistance results in a decreased shaft potential; the spreading dendritic depolarization becomes too weak to bring the spine heads in front of the wave to threshold. However, for intermediate values of spine stem resistance (solid curves), a “spike-diffuse-spike” chain reaction occurs, and the wave propagates. (b) Peak voltage versus stem resistance in spine head (dashed) and dendritic shaft (solid). (From Baer and Rinzel 1991; Fig. 3, with figure caption modified)

conductance load such as common branch points, attenuation of the potential and propagation failure is more likely. Spine densities (passive or excitable) also affect conductive loading and safety factor. A suitable spine density could ensure propagation through regions where the safety factor is low. More generally, propagation in regions of nonuniform loading may be complemented or counteracted by variations in

spine density; the dynamics of electrical current flow in cables with spines are dependent on spine distribution and spine morphology.

The continuum model has been applied to a variety of problems, for example, the dynamics of receptor potentials in mechanoreceptors (Bell and Holmes 1992) and the effect of noise on spiny dendrites (Coutts and Lord 2013), and more recently, the model was used to demonstrate

Dendritic Spines: Continuum Theory, Fig. 3 Spine clusters. Impulse propagation is contingent on the spatial distribution of spines. Effects of 3 spatial distributions of 24 excitable spines are compared in a cable of electrotonic length 2. Simulated electrode recording positions are $X = 0, 1$, and 2. Solid curves denote dendritic potentials, and dashed curves denote spine head potentials. Three spines near $X = 0$ are activated synaptically. (a) With a uniform but low density of spines ($\bar{n} = 12$ spines per e.l.), an impulse fails to propagate. (b) The same 24 spines are grouped into 8 clusters spaced 0.34 apart. Each cluster has

3 spines and width 0.04 ($\bar{n} = 75$ within a cluster). Impulse propagation is successful for this case. At $X = 1$ the simulated electrode recording is between spine clusters; hence, membrane potential is shown for the dendrite only. (c) The 24 spines are grouped into 4 clusters spaced 0.42 apart. Each cluster has 6 spines and width 0.08 (again, $\bar{n} = 75$ within a cluster). Here the impulse propagates to $X = 1$ but fails before reaching $X = 2$. Although the clusters have the same density as in (b), they are too far apart for successful propagation. (From Baer and Rinzel 1991; Fig. 4)

spatial delays and spatial memory effects in response to slow current ramps in a dendrite with excitable spines (Bilinsky and Baer 2018). The continuum theory of dendritic spines has been extended to study spine plasticity (Verzi et al. 2004), and it has spawned other computational approaches, including the spike-diffuse-spike model (Coombes and Bressloff 2003), originally intended as a computationally simple version of the Baer-Rinzel model.

Determining Network Structure from Data: Nonlinear Modeling Methods

Bjoern Schelter¹ and Marco Thiel²

¹Institute for Complex Systems and Mathematical Biology, University of Aberdeen, Aberdeen, UK

²Department of Physics, Institute for Complex Systems and Mathematical Biology, University of Aberdeen, Aberdeen, UK

Definition

In this entry we focus on inference of network structures from data. One possible approach to studying networks is to model the nodes, such as neurons, and generate networks and run simulations and observe the network behavior. This approach requires on a priori assumptions about the constituent parts; for instance, Hodgkin-Huxley neurons may be coupled and the resulting network behavior is investigated. The model behaviors can be compared to the measured neuronal signals through statistical analysis. However, this approach only provides indirect information about the network structure. An alternative approach to studying network structure is to use parametric, semiparametric, and nonparametric analyses of the observed signals and reconstruct the network connections. Such analyses are essential tools for systems in which network structure is not known, such as when anatomical connections are not known or information is not sufficient.

A particular challenge when inferring the network structure from data lies in the fact that analysis techniques to investigate interactions are often bivariate, investigating pairwise connections. Often, analyses cannot distinguish between direct and indirect interactions. A good measure of coupling between nodes should be able to distinguish direct and indirect interactions. To achieve this, a multivariate data analysis approach needs to be used. For linear systems multivariate data analysis approaches have been developed over the past decades. However, for nonlinear

systems, the development of multivariate analysis techniques is in its infancy. Nonlinear approaches typically require computationally intensive algorithms and large data sets which have limited their application.

In this entry, we provide a survey of approaches for inferring the network structure from nonlinear systems using nonlinear data-based modeling.

Detailed Description

Introduction

Mathematicians and physicists often generate models of complex networks starting with first principles. However, for complex biological systems found in neuroscience, the dynamics of neuronal behavior underlying the measured signals is poorly understood, leaving an approach based on first principles ideal. Therefore, an understanding of the behavior can only be based upon the analysis of measured data of the dynamics, i.e., time series from EEG or other population level signals, and point processes, from action potential timing. This approach is called data-based modeling.

Time series and point process analysis have different roots originating in mathematics, physics, and engineering. The underlying assumptions of the sources of the signals are different resulting in different approaches to the analysis. In mathematical statistics, the model has been based on linear stochastic systems; in physics the models have been of nonlinear deterministic systems. While methodological developments evolved independently across disciplines, over the past decade cross-fertilization has resulted in novel approaches to data-based modeling of nonlinear stochastic systems (Schelter et al. 2006b).

Reconstruction of networks depends on the detection of coupling between areas, particularly *causal influences* between two different processes, for instance, between brain areas or between brain areas and the periphery. The goal is to detect changes in coupling that may be caused by the underlying diseases. Detection of changes in coupling may lead to improved diagnosis and treatment strategies especially for neurological diseases.

The approach proposed here considers the brain as a dynamic system from which we measure the activity through the electroencephalogram (EEG), magnetoencephalogram (MEG), or another representation of the underlying neuronal activity. By applying the network analysis to the data sets recorded from normal patients and those suffering from neurological diseases, we hope to gain an understanding of the underlying mechanisms generating these dysfunctions (Volkman et al. 1996; Tass et al. 1998; Hellwig et al. 2001). However, there is a wide variety of applications beyond neurosciences to which the linear as well as nonlinear data analysis techniques presented here can be applied successfully.

Various linear analysis techniques have been proposed to determine interdependency between dynamic processes and to determine causal influences in multivariate systems (Schelter et al. 2006a). Using the Fourier transform, a signal can be converted to the frequency domain and the interdependencies analyzed using the cross-spectrum and coherence. But these tools are not sufficient to adequately describe interdependence within a multivariate system where correlation arises not because the two are directly coupled but because they receive common inputs. To enable a differentiation between direct and indirect influences in multivariate systems, multivariate linear approaches have been developed (Dahlhaus 2000; Baccala and Sameshima 2001; Ding et al. 2006).

Furthermore, multivariate network analysis can uncover directed interactions, which enables deeper insight into the basic mechanisms underlying such networks. These tools can determine not only if nodes are connected but the direction of the connection. In some cases in which communication is present in both directions, it is possible that they can communicate in distinct frequency bands. To detect directed nonlinear connections, appropriate analysis techniques are needed. Granger causality (Granger 1969) is utilized to determine causal influences when the coupling is linear. This probabilistic approach to determining causality is based on the principle that a cause precedes the effect in time and this is formulated in terms of predictability. Granger

causality is done by fitting autoregressive models to the signals and determining if the error in prediction of the next time point of one signal can be improved by the knowledge of the other. A graphical approach for modeling Granger-causal relationships in multivariate processes has been discussed (Eichler 2007). More generally, networks may be determined by the use of Granger causality between the nodes, but unlike linear cross-correlation, this approach tries to address spurious causalities caused by confounding by unobserved processes (Eichler 2005).

Nonlinear systems can show behaviors that are impossible in linear systems (Pikovsky et al. 2001); for example, nonlinear systems can synchronize. In the seventeenth century, Huygens observed synchronization between two pendulum clocks on the same wall. These clocks are coupled self-sustained oscillators. The process of synchronization is an adaptation of certain characteristics of the two processes. The oscillations between the clocks were always antiphase and restored synchronization after being perturbed (Pikovsky et al. 2000); for general systems, different phase relations are conceivable. A weaker form of synchronization has been observed between two coupled chaotic oscillators. These oscillators can synchronize their phases while their amplitudes stay almost uncorrelated (Pikovsky et al. 2001; Boccaletti et al. 2002; Wiesenfeldt et al. 2001). Several forms of synchronization have been described, ranging from phase synchronization via lag synchronization to almost complete synchronization (Boccaletti et al. 2002). Generalized synchronization is the most general case where one signal is related to the other through any arbitrary function.

While a battery of various analysis techniques is available for linear stochastic systems, for nonlinear systems techniques are still in their infancy. This entry is dedicated to the inference of the network structure based on the observation of nonlinear processes utilizing nonlinear data-based modeling approaches. The entry is subdivided into Phase-Based Approaches, Recurrence-Based Approaches, Information Theoretic Approaches, and Linear Approaches. We should note that it is

impossible to provide a complete survey of all approaches.

We begin this entry by introducing the general concept underlying most of the approaches to provide a quick introduction into the topic.

General Concept

One challenge when inferring the network structure from data lies in distinguishing direct and indirect interactions. Given a network with direct and indirect interactions, a bivariate analysis can be applied to every pairwise combination of nodes of the network to detect all connections. The resulting network could be fully connected. But the indirect connections are often weaker than direct ones. By setting some finite statistical power, we can hope to distinguish the direct ones from the indirect ones. But such an approach indeed relies on the assumption that indirect connections are the weakest in the network and that the statistical power is actually too low to detect the interaction. In general, both assumptions are not valid and bear the risk that erroneous conclusions are drawn; this leads to several *false-positive* conclusions.

Multivariate approaches attempt to correct for these problems with bivariate approaches. The theory behind multivariate approach is that if all contributing processes have been observed, it should be possible to infer whether or not a connection is indirect. This is done by partializing the information of the third processes. Practically, there are several approaches to do this. Here, we just provide an outline for how this is done. To test if two systems are direct or indirect, we will first assume for simplicity that there are only the two systems in question and one other system that could potentially influence them. Because we have observed all the systems, it is possible to determine the amount of information transfer from the third system onto the two systems of interest. If this extra information from the third process suffices to fully explain the information transfer between the first two systems, then we can conclude that the connection is indirect. If the third cannot explain all the information transfer, then we conclude that they are directly connected.

Whether the connection between the two systems of interest is causal can be determined by only using past points of each process to predict the future behaviors of the other processes.

In the following, we present some concepts how the partialization is performed in practice. A complete coverage of all possible approaches is beyond the scope of this entry.

Phase-Based Approaches

Synchronization analysis is a common approach to detect interactions between nonlinear self-sustained oscillators (Pikovsky et al. 2001). Following the observations and pioneering work of Huygens, the synchrony has been observed in many different systems including systems with a limit cycle or a chaotic attractor. Several different types of synchronization have been observed for these systems, ranging from phase synchronization, as the weakest form of synchronization via lag synchronization, to generalized or complete synchrony (Rosenblum et al. 1996; Rosenblum et al. 1997; Kocarev and Parlitz 1996; Pecora and Carroll 1990).

Phase synchronization analysis is a powerful tool because it detects even weak coupling between oscillators. For example, in some chaotic oscillators, very weak coupling between oscillators can synchronize their phases but not their amplitudes (Rosenblum et al. 1996). To quantify the process of synchronization, different measures have been proposed (Tass et al. 1998; Mormann et al. 2000; Rosenblum et al. 2001). The first approach presented here is a measure based on circular statistics, which is the so-called mean phase coherence (Mormann et al. 2000). We will introduce it by first reviewing phase synchronization that in weakly coupled self-sustained oscillators. For a more detailed introduction to synchronization including phase synchronization, we refer to the literature, e.g., Pikovsky et al. (2001).

Self-Sustained Oscillators

To discuss synchronization, we must start with a simple model of each node. One of the simplest

behaviors with nonlinear dynamics is a self-sustained oscillator. In general these oscillators can be described using the very general differential equation:

$$\dot{\mathbf{X}}(t) = f(\mathbf{X}(t), \alpha(t), U(t)),$$

where $\mathbf{X}(t)$ is a multidimensional variable to ensure an oscillatory behavior. The external influence $U(t)$ as well as the parameters $\alpha(t)$ are vectors. In this case, external driving is neglected in the following and the parameters α_i are assumed to be constant in time.

Two coupled oscillators can be written as follows:

$$\begin{aligned}\dot{\mathbf{X}}_1(t) &= f_1(\mathbf{X}_1(t), \alpha_1) + \epsilon_{1,2} \mathbf{h}_1(\mathbf{X}_1(t), \mathbf{X}_2(t)) \\ \dot{\mathbf{X}}_2(t) &= f_2(\mathbf{X}_2(t), \alpha_2) + \epsilon_{2,1} \mathbf{h}_2(\mathbf{X}_2(t), \mathbf{X}_1(t))\end{aligned}$$

where the coupling from oscillator j onto oscillator i is the coefficient. If $\epsilon_{i,j}$ is nonzero, then the system is considered coupled. $\mathbf{h}_1(\cdot)$ and $\mathbf{h}_2(\cdot)$ are the coupling functions and can be any arbitrary function. Usually, diffusive coupling is assumed, i.e.,

$\mathbf{h}_1(\mathbf{X}_1(t), \mathbf{X}_2(t)) = (\mathbf{X}_2(t) - \mathbf{X}_1(t))$ and for $\mathbf{h}_2$ accordingly.

Phase Synchronization

The phase of a limit cycle oscillator is a monotonically increasing function with $\Phi(t)|_{t=pT} = p2\pi = p\omega T$, where p denotes the number of completed cycles, T is the time needed for one complete cycle, and ω is the eigenfrequency of the oscillator. But, more generally, we can consider the phase of any oscillation from a differential equation

$\dot{\Phi}_i(t) = \omega_i, i = 1, \dots, N$ where the ω_i are the frequencies of the uncoupled oscillators with i denoting the i -th oscillator.

Differential equations describing the phase in a coupled two-oscillator system with different frequencies n and m can be written as follows:

$$\begin{aligned}n\dot{\Phi}_1(t) &= n\omega_1 + \epsilon_{1,2}nH_1(\Phi_1, \Phi_2) \\ m\dot{\Phi}_2(t) &= m\omega_2 + \epsilon_{2,1}mH_2(\Phi_2, \Phi_1),\end{aligned}$$

which can be written as the phase difference between the two oscillators

$$\begin{aligned} n\dot{\Phi}_1(t) - m\dot{\Phi}_2(t) &= n\omega_1 - m\omega_2 \\ &+ \epsilon_{1,2}nH_1(\Phi_1, \Phi_2) \\ &- \epsilon_{2,1}mH_2(\Phi_2, \Phi_1) \end{aligned}$$

This equation represents the generalized phase difference (Pikovsky et al. 2001).

In the case of $\epsilon_{2,1} = \epsilon_{1,2}$ then $\Phi_{1,2}^{n,m} = n\Phi_1 - m\Phi_2$ and $\Delta\omega = n\omega_1 - m\omega_2$; the above differential equation can be rewritten as

$$\dot{\Phi}_{1,2}^{n,m}(t) = \Delta\omega + \epsilon_{1,2}H(\Phi_{1,2}^{n,m})$$

with a new periodic function $H(\cdot)$.

This differential equation has a fixed point characterized by the following equation:

$$\Delta\omega + \epsilon_{1,2}H(\Phi_{1,2}^{n,m}) = 0$$

In this case, the phase difference is constant with time. Thus, both phases maintain a fixed relationship and the system is considered to be $n:m$ phase synchronized.

If some stochastic influence is present in the oscillators, which in turn alters the phase difference dynamics, certain fluctuations are possible but these are restricted by an appropriately chosen constant, i.e.,

$$|\Phi_{1,2}^{n,m} \bmod 2\pi| \leq \text{const}$$

In this case there will be variability between the phases, but the phase synchronization will still be preserved.

The Mean Phase Coherence

If the weakly coupled self-sustained oscillators are phase synchronized, the above equation can be reformulated to yield a single number to quantify the phase synchrony.

If there is a sharp peak in the phase difference distribution of $\Phi_{1,2}^{n,m} \bmod 2\pi$, it indicates that two phases have a coherent motion; if the distribution is flat, then it indicates that the two have independently evolving phases. Based on circular statistics, the phase difference distribution can be quantified as follows:

$$|R_{12}^{n,m}| = \left| \frac{1}{T} \sum_{t=1}^T e^{i\Phi_{1,2}^{n,m}(t)} \right|$$

This quantity is normalized between 0 and 1 and will be one for perfectly synchronized phases and zero for independent signals (Tass et al. 1998; Mardia and Jupp 2000; Mormann et al. 2000).

Often the phase of a signal cannot be directly measured. In which case, we can use the Hilbert transform to calculate a 90° phase shifted version of the time series measured, with which we can use to calculate the instantaneous phase

$$X_h(t) = \frac{1}{\pi} P.V. \int_{-\infty}^{\infty} \frac{X(\tau)}{t - \tau} d\tau$$

where P.V. refers to Cauchy's principal value. This leads to

$$V(t) = X(t) + iX_h(t) = A(t)e^{i\Phi(t)}$$

where i is the imaginary number and through Euler's formula can be written as a complex exponent where $\Phi(t)$ is the phase. Alternative approaches to obtain the phases are conceivable based on, e.g., wavelet transformations (Le van Quyen et al. 2001; Bandrivskyy et al. 2004). Note that this transformation is applicable for signals in which a frequency is well defined; different approaches are needed for broad band signals (see below) or point processes (Smirnov et al. 2007).

Multivariate Phase Synchronization

If multiple signals are being analyzed, a multivariate phase synchronization, also referred to as partial phase synchronization, can be used. For an N -dimensional process, the following matrix of pairwise interactions can be generated:

$$R = \left(R_{ij}^{n,m} \right)_{i=1, \dots, N, j=1, \dots, N}$$

This is called the *synchronization matrix* containing all pairwise phase synchronization measures. The inverse $\mathbf{PR} = \mathbf{R}^{-1}$ of this matrix

leads to the definition of the $n:m$ partial phase synchronization index

$$R_{kl|Y} = \frac{|PR_{kl}|}{PR_{kk} PR_{ll}}$$

between oscillators k and l . It is conditioned on the remaining processes which are summarized as Y . It can be analytically shown (Dahlhaus 2000; Schelter et al. 2006b) that this matrix inversion partializes the information of the third processes, as introduced in the “General Concept” section. Indirect interactions are characterized by a vanishing partial phase synchronization. If the bivariate phase synchronization index R_{kl} is considerably different from zero while the corresponding multivariate partial phase synchronization index $R_{kl|Y}$ is approximately zero, then the connection is most likely due to indirect coupling between the processes k and l (Schelter et al. 2006b). A rigorous statistical test using natural surrogates or twin surrogates (Nawrath et al. 2010) can be used to determine significance.

Example

Three coupled stochastic Roessler oscillators (Roessler 1976) are an example of a system of weakly coupled self-sustained phase-coherent stochastic oscillators:

$$\begin{aligned}\dot{X}_j &= -\omega_j Y_j - Z_j + \left[\sum_{i, i \neq j} \varepsilon_{j,i} (X_i - X_j) \right] \\ &\quad + \sigma_j \eta_j \\ \dot{Y}_j &= \omega_j X_j + a Y_j \\ \dot{Z}_j &= b + (X_j - c) Z_j\end{aligned}$$

with $i, j = 1, \dots, 3$ and parameters are set to $a = 0.15$, $b = 0.2$, $c = 10$, $\omega_1 = 1.03$, $\omega_2 = 1.01$, and $\omega_3 = 0.99$ yielding chaotic behavior in the deterministic case. The noise term, η_j , is Gaussian distributed with mean of zero and standard deviation $\sigma_j = 1.5$. Both the bidirectional couplings between oscillators 1 and 3 and 1 and 2 are varied

between 0 and 0.3. The oscillators 2 and 3 are not directly coupled.

The 1:1 mean phase coherence and the partial phase synchronization indices are depicted in Fig. 1. The bivariate synchronization index mean phase coherence R_{12} , as well as R_{13} , increases for increasing coupling strength, indicating phase synchronization (Fig. 1a upper triangular). Once there is a sufficiently strong coupling between oscillators 1 and 2 as well as 1 and 3, indirect coupling is seen between 2 and 3 with a nonvanishing bivariate synchronization index R_{23} (Fig. 1a upper triangular). This high but spurious phase synchronization is caused by the common influence from oscillator 1. In the same figure (Fig. 1a below the diagonal), the results of partial phase synchronization analysis are shown. While $R_{12|3}$ and $R_{13|2}$ are essentially unchanged compared to the bivariate synchronization indices, $R_{23|1}$ stays almost always below 0.1 and therefore indicates this measure is due to spurious synchronization, indicating that there is an absence of a direct coupling between oscillators 2 and 3. Hence, the true underlying (multivariate) network structure is correctly revealed by the analysis (Fig. 1b).

Phase Dynamics Modeling

Another approach in reconstructing networks is to estimate the coupling functions $H_1(\Phi_1, \Phi_2)$ and $H_2(\Phi_2, \Phi_1)$ from observations of the dynamics. These reconstructions can, for instance, be based on approximating the functions H_1 and H_2 with trigonometric functions. With this approach, it has been shown that a reliable detection of interactions (Smirnov et al. 2007 and references therein) and therefore the reconstruction of the network topology are possible (Kralemann et al. 2011).

Recurrence-Based Approaches

If the processes are not phase-coherent, which is typically the case for many observed systems, the approach based on the direct calculation of the phases is not feasible because neither the phase nor the onset of phase

Determining Network Structure from Data: Nonlinear Modeling Methods, Fig. 1 (a) Phase synchronization as well as partial phase synchronization analysis. (b) Corresponding network as inferred from the observations

synchronization can be explicitly defined. Bivariate analysis of noncoherent systems has been approached by testing synchronization using alternate notion of the phase, i.e., a phase that builds on the general idea of curvature (Osipov et al. 2003). However, such a definition of the phase restricts the analysis to systems where the phase trajectory corresponds to a curve with a positive curvature on some projection plane. An alternative approach is based on recurrence analysis.

Recurrence Analysis

A synchronization measure based on the recurrences of a trajectory can also be used. This approach considers phase synchronization in a statistical sense. The notion of recurrences in phase space was originally introduced by Poincare (1890). A representation of these recurrences is given by the recurrence matrix (Eckmann et al. 1987; Marwan et al. 2007):

$$RP(\varepsilon)_{i,j} = \Theta(\varepsilon - \|\mathbf{X}(i) - \mathbf{X}(j)\|), i, j = 1, \dots, nn$$

where $\mathbf{X}(i)$ and $\mathbf{X}(j)$ denote trajectories of length n in phase space, $\Theta(\cdot)$ is the Heaviside function, $\|\cdot\|$ is an appropriate norm, and ε is a predefined threshold. If only a scalar time series has been observed, the state of the system, i.e., the vector $\mathbf{X}(i)$, can typically be reconstructed by delay embedding (Packard et al. 1980; Takens 1981; Sauer et al. 1991), where each dimension represents the data at some time lag τ in the past:

$$\mathbf{X}(i) = [\mathbf{X}(i), \mathbf{X}(i - \tau), \dots, \mathbf{x}(i - k\tau)]$$

When a series of points stays within a small distance apart, say within a small tube of radius ε around the other, that section of the trajectory corresponds to a diagonal of 1's in the recurrence matrix. Thus, an estimate of the probability

$$\hat{p}(\varepsilon, \tau) = RR_\tau(\varepsilon) = \frac{1}{L - \tau} \sum_{j=1}^{L-\tau} RP(\varepsilon)_{i,i+\tau}$$

that a system recurs to the ε -neighborhood of a former point of the trajectory after τ time steps is given by the diagonal-wise calculated recurrence rate $RR_\tau(\varepsilon)$.

This measure can be considered as a generalized autocorrelation function (Romano et al. 2005), since it also describes higher-order correlations among the points of the trajectory. It measures the adaptation of the time scales of two interacting systems by comparing their corresponding recurrence matrices; if the distances between diagonal lines in their recurrence matrices coincide, the time scales of the systems adapt to each other. To quantify this, the cross-correlation coefficient of the probabilities of recurrence can be calculated as follows:

$$CPR_{kl} = \langle \hat{p}_k(\varepsilon, \tau) \hat{p}_l(\varepsilon, \tau) \rangle, CPR_{kl} \in [0, 1]$$

In the case when the two systems have locked phase dynamics, the probability of recurrence is simultaneously high for both systems and the CPR_{kl} will differ from zero significantly. This synchronization measure has been demonstrated to be effective for detecting coupling in a general class of non-phase-coherent and nonstationary systems and even for time series corrupted by strong noise (Romano et al. 2005).

Multivariate Recurrence Analysis

Recurrence analysis can also be applied to a multivariate system with N interdependent and non-phase-coherent processes. To treat the multivariate case can be generated as a matrix of the bivariate CPR synchronization indices:

$$CPR = (CPR_{ij})_{i,j=1,\dots,N}$$

is used. This matrix has the same symmetry properties as the synchronization matrix for phasecoherent systems. Using the inverse

CPR^{-1} , the generalized partial synchronization index can be calculated:

$$CPR_{kl|Y} = \frac{|CPR_{kl}^{-1}|}{\sqrt{CPR_{kk}^{-1} CPR_{ll}^{-1}}}$$

This measure quantifies phase synchronization between two oscillators k and l , conditioned on third processes Y of a multivariate possibly non-phase-coherent and noisy oscillatory process (Nawrath et al. 2010).

Information Theoretic Approaches

Information theory-based approaches complement the nonlinear approaches presented above. The mutual information between time series X and Y can be calculated as follows:

$$I(X; Y) = \sum_{y \in Y} \sum_{x \in X} p(x, y) \log \frac{p(x, y)}{p(x)p(y)}$$

where $p(x)$ represents the probability that the signal X will have the amplitude x and $p(x, y)$ is the joint probability that the time series X will have the value x while simultaneously the time series Y will have the value y . Transfer entropy calculates the direction of information flow between two systems by testing how the information from the past of the two systems predicts the future of one of the signals:

$$T_{X \rightarrow Y}(k, l) = \sum p(y_{t+1}, y_t^{(k)}, x_t^{(l)}) \log \frac{p(y_{t+1} | y_t^{(k)}, x_t^{(l)})}{p(y_{t+1} | y_t^{(k)})}$$

This approach utilizes the fundamental concepts of the information theoretic approaches (Kantz and Schreiber 1997). The $p(y_{t+1} | y_t^{(k)}, x_t^{(l)})$ are the conditional probability density functions where the probability of y_{t+1} given the previous k points of the times series $y_t^{(k)}, x_t^{(l)}$.

The information and the transfer information as presented are bivariate; however multivariate extensions are straightforward as the (conditional) probability density functions can include more processes. The challenge in calculating these measures in higher dimensional densities is that they quickly become computationally intensive to find all the conditional probabilities. Solutions are possible and can, for instance, be found in Palus and Stefanovska (2003), Runge et al. (2012), or Wibral et al. (2012) and references therein.

Linear Approaches

Although linear approaches are strictly speaking not part of the nonlinear data-based modeling approaches, we include them here. They are indeed very powerful in revealing the true underlying network structure despite the fact that they are technically speaking not applicable. Due to space limitations, we can only discuss one of the linear approaches, although many more exist in the literature. We refer the reader, for instance, to Schelter et al. (2006a) and references therein.

The concept of Granger causality (Granger 1969) is based on the commonsense conception that causes precede their effects in time. Partial directed coherence

$$|\pi_{i \leftarrow j}(\omega)| = \frac{|A_{ij}(\omega)|}{\sqrt{\sum_m |A_{mj}(\omega)|^2}}$$

with

$$\mathbf{A}(\omega) = \mathbf{I} - \sum_{r=1}^p \mathbf{a}(r) e^{-i\omega r}$$

for an N -dimensional vector autoregressive process of order p (VAR[p] process)

$$\mathbf{X}(t) = \sum_{r=1}^p \mathbf{a}(r) \mathbf{X}(t-r) + \varepsilon(t),$$

where $\varepsilon(t)$ is a multivariate Gaussian white noise process with covariance matrix Σ . This measure

was introduced by Baccala and Sameshima (2001) as a measure of Granger causality.

Partial directed coherence $|\pi_{i \leftarrow j}(\omega)|$ provides a measure for the directed, linear influences from $X_j(t)$ onto $X_i(t)$ at frequency ω . It is estimated by fitting an N -dimensional VAR[p] model to the data and directly using the above equations with the parameter estimates substituted for the true parameters.

Particularly important for nonlinear systems is the corresponding pointwise α -significance level for the partial directed coherence (Schelter et al. 2006c)

$$\left(\frac{\hat{C}_{ij}(\omega) \chi_{1,1-\alpha}^2}{n \sum_m |\hat{A}_{mj}(\omega)|^2} \right)^{1/2}$$

where $\chi_{1,1-\alpha}^2$ is the $1-\alpha$ quantile of the χ^2 -distribution with one degree of freedom. The values

$$C_{ij}(\omega) = \sum_{ii} \left[\sum_{l,m=1}^p H_{ij}(l,m) \right.$$

$\left. (\cos(l\omega) \cos(m\omega) + \sin(l\omega) \sin(m\omega)) \right]$ can be calculated based on the inverse $\mathbf{H} = \mathbf{V}^{-1}$ of the covariance matrix $\mathbf{V}$ of the VAR[p] process $\mathbf{X}(t)$, which is composed of the entries

$\mathbf{V}_{ij}(l, m) = \text{cov}(X_i(t-l), X_j(t-m))$ for $i, j = 1, \dots, N$ and $l, m = 1, \dots, p$ (Luetkepohl 1993).

We emphasize that the significance level depends on the order of the vector autoregressive process; higher model orders lead to higher significance levels which in turn indicates that for higher models the ability to detect weak couplings decreases.

Partial directed coherence by construction is a multivariate analysis technique. It has been developed for linear stochastic processes. However, in neurophysiology, nonlinear stochastic processes are generating the time series. In most of these cases, the dependence structure is reflected in the linear second-order structure; for this reason the partial directed coherence discloses the network structure also for nonlinear processes.

As an example system for which to test these tools, we will introduce a system of coupled stochastic van der Pol oscillators (van der Pol 1922):

$$\begin{aligned}
\ddot{X}_1 &= \mu(1 - X_1^2)\dot{x}_1 - \omega_1^2 X_1 + \sigma\eta_1 + \varepsilon_{12}(X_2 - X_1) + \varepsilon_{13}(X_3 - X_1) + \varepsilon_{14}(X_4 - X_1) \\
\ddot{X}_2 &= \mu(1 - X_2^2)\dot{x}_2 - \omega_2^2 X_2 + \sigma\eta_2 + \varepsilon_{23}(X_3 - X_2) + \varepsilon_{24}(X_4 - X_2) + \varepsilon_{21}(X_1 - X_2) \\
\ddot{X}_3 &= \mu(1 - X_3^2)\dot{x}_3 - \omega_3^2 X_3 + \sigma\eta_3 + \varepsilon_{34}(X_4 - X_3) + \varepsilon_{31}(X_1 - X_3) + \varepsilon_{32}(X_2 - X_3) \\
\ddot{X}_4 &= \mu(1 - X_4^2)\dot{x}_4 - \omega_4^2 X_4 + \sigma\eta_4 + \varepsilon_{41}(X_1 - X_4) + \varepsilon_{42}(X_2 - X_4) + \varepsilon_{43}(X_3 - X_4)
\end{aligned}$$

where the oscillators are given coefficients $\omega_1 = 1.5$, $\omega_2 = 1.48$, $\omega_3 = 1.53$, $\omega_4 = 1.44$, $\sigma = 1.5$, and Gaussian distributed white noise η_i . This system is simulated for $n = 50,000$ data points for each process to generate signals to apply the tools for reconstructing the network topology. Note that although the four oscillators are diffusively coupled and therefore their interactions are still linear, the system is nonlinear. The nonlinearity parameter μ is fixed to $\mu = 5$, leading to a highly nonlinear behavior of the van der Pol oscillators. The unidirectional and bidirectional couplings between these four nonidentical oscillators are

set to $\varepsilon_{12} = \varepsilon_{21} = 0.2$, $\varepsilon_{24} = \varepsilon_{42} = 0.2$, $\varepsilon_{31} = 0.2$, and $\varepsilon_{34} = 0.2$.

The causal influences are summarized in the graph in Fig. 2a. Estimated partial directed coherences as well as the spectra are given in Fig. 2b. The order of the vector autoregressive process is chosen to be $p = 200$. This high model order is required to reproduce the spectra with sufficient accuracy, as opposed to nonparametric spectral estimates. The corresponding 5% significance levels are indicated by gray lines. Partial directed coherence correctly detects the causal influences in the van der Pol system. Note that the significance level depends on the

Determining Network Structure from Data: Nonlinear Modeling Methods, Fig. 2 Causal influences for the example of four coupled stochastic van der Pol oscillators (a). Corresponding spectra (diagonal) and partial directed coherence (off-diagonal) (b). The

corresponding 5% significance levels are indicated by gray lines. The simulated causal influences are reproduced correctly since only those partial directed coherences that correspond to direct interactions are statistically significant at the oscillation frequencies

investigated frequency. At the peaks in the spectra of the van der Pol oscillators, the significance level is slightly higher than at the remaining frequencies. Thus, only those partial directed coherencies are statistically significant that correspond to a direct causal influences between the oscillators.

Application

So far, the multivariate analysis techniques presented here have been applied to simulated time series. To illustrate their performance in physiological applications, examples of patients suffering from essential tremor are presented.

The pathophysiological basis of essential tremor, a common neurological disease with a prevalence of 0.4–4% (Louis et al. 1998), is not precisely known. Essential tremor manifests

itself mainly in the upper limbs, when the hands are in a postural outstretched position. Usually the trembling frequency of the hands is 4–10 Hz. To elucidate the tremor generating mechanisms in essential tremor, relationships between the brain and trembling muscles are of particular interest. For unilaterally activated tremor, tremor-correlated cortical activity to the contralateral tremor side has been revealed by magnetoencephalography (MEG) and electroencephalography (EEG) for Parkinsonian tremor (Volkmann et al. 1996; Hellwig et al. 2001) and by electroencephalography for essential tremor (Hellwig et al. 2001). In bilaterally activated essential tremor, however, a more complex interrelation structure has been observed by simultaneous electroencephalographic recordings from the scalp and electromyographic (EMG) recordings from the extensor muscles (Hellwig et al. 2003). In addition to contralateral coherences,

Determining Network Structure from Data: Nonlinear Modeling Methods, Fig. 3 Partial directed coherence analysis for a patient suffering from essential tremor. A significant influence from the *right EEG* onto the

left EMG (3rd row/1st column), from the *left EMG* onto the *right EEG* (1st row/3rd column), from the *left EEG* onto the *right EMG* (4th row/2nd column), and from the *right EMG* onto the *left EEG* (2nd row/4th column) is detected

also ipsilateral coherences between the sensorimotor cortex and the muscles have been detected.

In this study, patients were seated in a comfortable chair having their forearms supported while their hands were outstretched to activate tremor. Data were sampled at 1,000 Hz. The EEG data as well as the EMG data were preprocessed applying a band-pass filter between 30 and 200 Hz to avoid aliasing and movement artifacts; the EMG was rectified afterward. The EEG was then high-pass filtered above 0.5 Hz to avoid baseline fluctuations and also anti-aliasing filtered. Scalp electrodes over the left and right sensorimotor cortex and the EMG of the left and right wrist extensor are analyzed.

It is of importance to investigate whether the cortex imposes its oscillatory activity on the muscles via the corticospinal tract or whether the muscle activity is just reflected in the cortex via proprioceptive afferences. To get these deeper insights into the tremor generating mechanisms, partial directed coherence is applied to data recorded from these patients.

In Fig. 3, the results of the partial directed coherence analysis for the two EMG and the two EEG channels are shown for an exemplary patient. Both directions from the cortex to the muscles and vice versa are observed. A significant influence from the right EEG onto the left EMG, from the left EMG onto the right EEG, from the left EEG onto the right EMG, and from the right EMG onto the left EEG is detected. Especially, the partial directed coherence from the right EMG to the left EEG is rather large.

The graph summarizing the results of partial directed coherence analysis for the essential tremor patient is presented in Fig. 4. The influences between both EEGs are marked by dashed arrows. This is due to the fact that partial directed coherence is not significant exactly at the tremor frequency but over a range of frequencies close to the tremor frequency. Since causal influences from both EEGs to the corresponding contralateral EMGs are present, participation of the motor cortex in tremor generation is strongly indicated. Moreover, there is also a significant partial directed coherence from the EMG to the contralateral EEG at the tremor

Determining Network Structure from Data: Nonlinear Modeling Methods, Fig. 4 Graph for partial directed coherence analysis of the tremor application of Fig. 3. The arrows indicate a direct and directed interrelation at the tremor frequency. The dashed arrows indicate possible interactions between the EEGs that could not be unambiguously shown

frequency. This corresponds to a feedback from the muscles to the somatosensory cortex. For both patients, unexpected ipsilateral interrelations are not detected by partial directed coherence analysis.

Summary

Several approaches to data-based modeling are conceivable. In this entry, we focused on a few multivariate approaches that enable to distinguish direct from indirect interactions. Some even provide directions for the interactions, for instance, Granger-causality-based concepts. In applications to observed nonlinear systems, the type of data, its dimension, noise contamination, and stationarity typically decides which technique can be applied and what conclusions can be drawn. Typically, simulation studies tailored to the problem at hand should be performed prior to any analysis.

Definition

A deterministic reaction-diffusion simulator is a software designed to approximate the dynamics of a system governed by the diffusion and interaction

of species within or across domains in a deterministic fashion.

Detailed Description

In a neural tissue, much physiological activity is governed or moderated by diffusion and interaction of many types of molecules and ions. Intracellularly, signaling molecules and ions such as cAMP, G-proteins, and calcium diffuse and moderate the activity of ion channels and other proteins. They also interact with receptors on organelles, as seen with calcium-induced calcium release. Extracellularly, bulk diffusion of glutamate, calcium, sodium, and potassium has both pathological and physiological effects. In addition to diffusion through the aqueous media of intracellular and extracellular space, there is also diffusion of signaling molecules and of ion-channel-forming proteins within the membrane. Modeling and simulating such complex reaction-diffusion systems accurately is needed for the mechanistic understanding of these processes.

Historically, reaction-diffusion simulators were developed to dissect the role of different molecules in signaling pathways and have been used by the systems biology community. In the past, most neural electrophysiology models were either kept completely separate from reaction-diffusion systems or used only simple approximations to implement phenomenological effects. Realizing the importance of coupling reaction-diffusion with excitability models, several tools have now been developed to handle it at various levels of detail. Most of these simulators provide options of running the simulations in a deterministic, stochastic, or hybrid manner. However, each of those simulations requires users to choose specific options which best describe the system. For example, stochastic simulations are more suitable when a small number of molecules are involved and high-resolution dynamics are required, whereas deterministic simulations suffice when a large number of molecules are involved and low-resolution dynamics are expected to give good approximation. Hybrid simulations allow to speed up the computations by using deterministic steps for the molecules

that are large in numbers and stochastic steps for molecules that are small in numbers.

Theory

Deterministic simulators are most appropriate when each compartment has a large number of molecules, either because the concentration is sufficiently high (e.g., sodium ions in a neuron) or because the compartment is sufficiently large. Either way, the law of large numbers (Kotelenez 1986) applies when many ions or molecules are present so that the dynamics of the population can be well approximated by the mean dynamics.

This assumption of large numbers underlies the key trade-off between deterministic and stochastic simulators. Deterministic simulations allow the use of a single number to represent the concentration in a given volume over a relatively large time step in the setting of large numbers of particles. Stochastic simulations are needed when the number of molecules is small, but exact stochastic methods generally require either a state variable for each molecule (which is computationally expensive) or small time steps (Kerr et al. 2008; Rathinam et al. 2003).

Fick's second law of diffusion states that the diffusion of a species with concentration u at position x (in one, two, or three dimensions) and time t within a domain is governed by

$$u_t = D\nabla^2 u \quad (1)$$

which states that the rate of change of concentration at a given point and time is proportional (with proportionality constant D , the diffusion constant) to the Laplacian of the concentration u , a measure of its unevenness. A reaction-diffusion equation for a single species is the diffusion equation except with an additional term $f(u, t)$ added to the right-hand side to describe reactions:

$$u_t = D\nabla^2 u + f(u, t) \quad (2)$$

When multiple species are present, the system of partial differential equations (PDEs) consists of many equations of this form, where the reaction

term may depend on all species present. Initial and boundary conditions complete the mathematical description (Fife 1979). In neuroscience, Neumann boundary conditions are common, as they describe the flux across the boundary, such as occurs through ion channels.

Practice

A reaction-diffusion simulator must specify the following: (1) **domains**, discretized volumes, areas (membranes), or lines (for 1D diffusion down a neurite); (2) **species**, molecules or ions that can be assigned to different domains; (3) **reactions**, among diffusion species or with fixed sites; and (4) **rates** of reactions and of diffusion (diffusion rates will differ among species).

Although diffusion is defined by a PDE (Eq. 1), most simulators internally convert all the PDEs into ordinary differential equations (ODEs) and from there to difference equations. The equations are typically solved using one of the three strategies: finite difference, finite elements, or finite volumes. Finite difference is the most mathematically straightforward, but unlike the other two strategies, it requires a uniform grid. Finite element methods assume concentration varies in a piecewise linear or nonlinear (based on spatial pattern) fashion within each element. Finite volume methods assume each volume is well-mixed which helps ensure conservation of mass.

A few commonly used deterministic reaction-diffusion simulators within the broader computational biology community are COMSOL (COMSOL Inc. www.comsol.com), COPASI (Hoops et al. 2006), FEniCS (Langtangen and Logg 2016), Morpheus (Starruß et al. 2014), and Virtual Cell (Loew and Schaff 2001). Both COMSOL and FEniCS are general-purpose PDE simulators, which provide a variety of functions to create different types of meshes and to simulate reaction-diffusion dynamics with discretized elements. COMSOL provides implicit and explicit methods for solving ODEs to tackle stiff and nonstiff problem. Additionally, it also includes

an advanced library of solvers (LAPACK, MUMPS, PARDISO, SPOOLES, Damped Newton methods, Double Dogleg, etc.) to tackle linear and nonlinear algebraic systems. FEniCS supports the creation of complex meshes using a technique called *constructive solid geometry*, which allows defining geometry in terms of simple shapes and set operations: union, intersection, and set difference. By default, FEniCS uses sparse LU decomposition (Gaussian elimination) to solve linear systems of differential equations. The interface with *linear algebra backends* allows using a variety of preconditioned Krylov solvers (iterative methods) for solving larger systems. A few of the methods are biconjugate gradient, conjugate gradient, generalized minimal residual, minimal residual, Richardson, parallel sparse LU, transport-free quasi-minimal residual, and UMFPACK. COPASI allows arbitrary discrete events for convenient interaction with the model. It also uses variably sized compartments to specify domains. Though COPASI is mainly a stochastic simulator, it allows deterministic simulations via LSODAR algorithm (Hindmarsh and Petzold 2005). Morpheus is a modeling and simulation environment for the study of multi-scale and multicellular systems. It allows coupling ODEs, PDEs, and cellular Potts models in 2D or 3D. It implements finite difference methods, Euler, Heun, and Runge-Kutta (RK4), all with fixed time step. Virtual Cell has been used to develop signaling pathway models in a large variety of cell types. It simulates on one-, two-, or three-dimensional domains specified either analytically or via segmented images discretized using a regular Cartesian mesh. It supports a variety of explicit, implicit, and semi-implicit finite volume methods. Although these simulators provide great functionality to study molecular pathways and related neurological phenomenon, they are not primarily designed to simulate electrophysiology models.

GENESIS (Bower et al. 2013), MOOSE (Ray and Bhalla 2008), NEURON (Carnevale and Hines 2006), and STEPS (Hepburn et al. 2012) allow coupling between reaction-diffusion system and electrophysiology models. Historically, general neural modeling software like GENESIS,

MOOSE, and NEURON allowed 1D longitudinal diffusion between compartments, which could be extended to 2D diffusion by specifying concentric shells within a compartment and writing equations for diffusion between adjacent shells.

These simulators have all now been extended to permit more general reaction-diffusion solutions: Chemesis (Blackwell and Kotaleski 2003) for GENESIS, Kinetikit (Vayttaden and Bhalla 2004) for MOOSE, and RxD (McDougal et al. 2013) for NEURON. In Chemesis, numerical methods for both reactions and diffusion use the GENESIS solvers and thus typically employ the exponential Euler method. Earlier version of Kinetikit used exponential Euler; however, Kinetikit 12 uses adaptive time-step fifth-order Runge-Kutta-Fehlberg from the GNU Scientific Library. NEURON RxD supports first- and second-order implicit fixed-step integration via implicit Euler and Crank-Nicolson (Crank and Nicolson 1996), respectively. NEURON also supports variable-step variable-order implicit methods from the SUNDIALS library (Hindmarsh et al. 2005). In addition to providing a user-friendly interface for modeling reaction-diffusion in NEURON, RxD also allows the specification of arbitrary spatial and volumetric domains. Three-dimensional extracellular simulations (Newton et al. 2018), solved using a parallelized Douglas-Gunn Alternating Direction Implicit method (DG-ADI) (Douglas and Gunn 1964), incorporate the effects of extracellular structures as local changes to the free volume fraction and tortuosity.

STEPS is primarily a stochastic simulator, but it also allows both deterministic and hybrid simulations. Reaction-diffusion in STEPS requires well-mixed volumes in the form of tetrahedrons. Any reconstructed 3D neuronal morphology can be used to specify arbitrary domains and then can be discretized into tetrahedrons using external software. STEPS supports deterministic spatial reaction-diffusion solutions by solver “TetODE,” which is based on the CVODE library.

Definition

The diffusion equation (DE) is a second-order parabolic partial differential equation describing mass transport phenomena due to thermal motion of particles (Crank 1975).

Detailed Description

Diffusion is an important transport mechanism in neurons (Bloodgood and Sabatini 2005; Ehlers et al. 2007; Korkotian and Segal 2006; Makino and Malinow 2009; Qian and Sejnowski 1988; Renner et al. 2009; Sabatini et al. 2002; Santamaria et al. 2006; Schmidt et al. 2007a. Smith et al. 1993; Soler-Llavina and Sabatini 2006). It takes place in the cytosol, the cell membrane and the endoplasmic reticulum. Subject to diffusion are both ions (Ca^+ , Na^+ , K^+ , Cl^- , etc) and large complex molecules (lipids, proteins, DNA, RNA, etc.). The physical process of diffusion in absence of any chemical reactions is described by the diffusion equation:

$$\frac{\partial C(\mathbf{x}, t)}{\partial t} = \nabla \cdot (D(\mathbf{x}, t) \nabla C(\mathbf{x}, t))$$

where D is the diffusion coefficient (diffusivity) and C is the concentration.

In the case of constant isotropic diffusion coefficient, the DE,

$$\frac{\partial C}{\partial t} = D \nabla^2 C = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

is separable.

In the one-dimensional case, the DE becomes

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2}$$

For an initial amount of substance M released at $t = 0$ and $x = 0$, assuming that $C \rightarrow 0$ as $x \rightarrow \pm \infty$, the solution to the one-dimensional DE is given by

$$C(x, t) = \frac{M}{\sqrt{4\pi Dt}} e^{((-x^2)/4Dt)}$$

and the mean square displacement (MSD) of the diffusing particles is a linear function in time $MSD \sim t$.

There are two approaches to deriving the DE: the phenomenological and the atomistic (Philibert 2005). The phenomenological

approach employs Fick's first law, stating that the flux of particles J is proportional to the gradient of the concentration

$$J = -D \frac{\partial C}{\partial x}$$

Since particles cannot be created or destroyed in the process, the flux of particles into a region must be equal to the particle flux out of the region, i.e., particles must satisfy the continuity equation:

$$\frac{\partial C}{\partial t} + \nabla \cdot J = 0$$

Combining Fick's first law with the continuity equation yields $\partial C / \partial t = \nabla \cdot (D \nabla C)$

Another way of deriving the diffusion equation is by introducing the concept of the random walk. Consider a particle moving along the real line starting at $t = 0$ and $x = x_0$. At each time step Δt , the particle can make a jump left or right at a distance Δx with equal probability.

Then the probability for the particle to be at position x at time $t + \Delta t$ will be

$$p(x, t + \Delta t) = \frac{1}{2} p(x - \Delta x, t) + \frac{1}{2} p(x + \Delta x, t)$$

Combining the Taylor expansions of the left and the right hand sides

$$p(x, t + \Delta t) = p(x, t) + p_t(x, t) \Delta t + O(\Delta t^2)$$

$$p(x \pm \Delta x, t) = p(x, t) \pm p_x(x, t) \Delta x + \frac{1}{2} p_{xx}(x, t) \Delta x^2 + O(\Delta x^3)$$

in the limit $\Delta t \rightarrow 0$ and $\Delta x \rightarrow 0$ leads to where

$$D = \lim_{\Delta t \rightarrow 0, \Delta x \rightarrow 0} \frac{\Delta x^2}{\Delta t}$$

Reaction-Diffusion Equation

In the presence of chemical reactions, additional terms (usually nonlinear) reflecting the various chemical reactions in the system can be added to the diffusion equation. Such a generalized

variation of the diffusion equation is known as the reaction-diffusion equation:

$$\frac{\partial C_A(x, t)}{\partial t} = \nabla \cdot (D_A(x, t) \nabla C_A(x, t)) + \sum_{i=1}^N f_i(C_A, R_i)$$

where R_i are the reactants interacting chemically with substance A.

Anomalous Diffusion

Random walks with biased jump probabilities give rise to the so-called anomalous diffusion. In that case, the MSD of the diffusing particles is a power law, i.e., $MSD \sim t^\alpha$. The regime with $0 \leq \alpha \leq 1$ is called subdiffusion, and the regime with $\alpha > 1$ is called superdiffusion (Metzler and Klafter 2000).

Anomalous diffusion can be described in terms of fractional calculus, i.e., the anomalous diffusion equation can be written as

$$\frac{\partial^\alpha C}{\partial t^\alpha} = D \frac{\partial^2 C}{\partial x^2}$$

where the fractional derivative of the Riemann-Liouville type for is given by

$$D_t^\alpha f(t) = \frac{1}{\Gamma(1-\alpha)} \frac{d}{dt} \int_0^t \frac{f(\tau)}{(t-\tau)} d\tau$$

Applications

Diffusion in neurons has been modeled using 1D to 3D approximations with stochastic and differential equation models (Santamaria et al. 2006; Santamaria et al. 2010; Santamaria et al. 2011; Bressloff and Earnshaw 2009; Brown et al. 2008; Jedlicka et al. 2011; Schmidt et al. 2007b; Holcman and Triller 2006). A large number of studies have concentrated in the diffusion of intracellular calcium ions. Calcium ions can activate potassium channels or act as second messengers in biochemical cascades activated by synaptic activity.

Differential Versus Stochastic Simulation

It could be confusing that the same physical process can be modeled with two frameworks. Choosing between modeling using differential equations or a stochastic process depends on the nature of the problem. The differential equation diffusion model is amenable to be applied to compartments as those used in modeling the electrical activity of neurons. The fundamental properties of the equation are identical to those of the cable equation. When using more complex dendritic structures, solving the diffusion equation becomes computationally expensive. A reality check has to be performed when using differential equation since the volumes being investigated could be very small and the concentrations could be in the nanomolar range. If the concentrations being modeled are equivalent to fractions of molecules that would call into question the results of the simulations, especially if there are biochemical reactions involved.

The stochastic simulation strategy is used when the model is tracking the position of individual molecules or small groups of molecules. In this case boundary conditions are solved by assuming that particles collide and are reflected. Although highly accurate, this process could become computationally intractable for large sections of dendritic tree being modeled and is not easily integrated into compartmental models of electrical activity.

Shell Approximation

In compartmental modeling the electrical variables (conductances, voltages, and currents) are homogeneous through the compartment (Jedlicka et al. 2011). However, if calcium ions flow into the cell, they could diffuse to the center of the dendrite or along the dendrite. To simulate this mechanism, the problem is simplified to a 2D diffusion process. Within a single compartment, it is assumed that the concentration of a molecule will be homogenous along the radial axis of the compartment; thus, the volume is divided into concentric shells. Diffusion takes place between contiguous shells with each shell potentially having immobile buffers. Diffusion from one compartment to its neighbors has been implemented on shells of the

same level across compartments. Thus, each compartment has the same number of shells, but not all shells have the same thickness due to variations in the diameter of each compartment.

Stochastic Approximation

The diffusion of molecules inside a dendrite can be modeled with a random walk. Each molecule is characterized by a diffusion coefficient. From this diffusion coefficient, a random number generator chooses distances to move along a random direction. The average movement of the particle can be described with the stochastic version of the diffusion coefficient ($\text{MSD} \sim t$). If a particle collides with a membrane, then the molecule is reflected and continues its movement. This type of modeling can be used to study the diffusion of ions and proteins in dendrites and spines. The shapes of dendrites can be modeled or obtained from serial electron microscope reconstruction. The same strategy has been used to study the lateral mobility of glutamate receptors in and out of a synapse.

Modeling Anomalous Diffusion

The fundamental assumption to use the stochastic or differential equation models of diffusion is that molecules are moving without any memory of their past. This is called a Markovian process. However, the complex structure of dendrites can impose correlations in the diffusing molecules. For example, when molecules move along dendrites, they can enter a spine. Due to the spine bottle-neck produced by the spine head to neck diameter ratio, the molecule remains trapped in the spine for a random period of time. Once the molecule escapes one spine, it can then be trapped by another spine. If the dwell time in each spine varies widely, then the position of the molecule along the dendrite can no longer be assumed to be Markovian. Instead, the diffusion of the molecules becomes correlated due to the density of spines and their shape. It has been experimentally shown that this process causes anomalous diffusion in Purkinje and hippocampal pyramidal cells (Santamaria et al. 2006, 2011).

Digital Filtering

Roemer van der Meij and Jan-Mathijs Schoffelen
Donders Institute for Brain, Cognition and Behaviour,
Centre for Cognition, Radboud University Nijmegen,
Nijmegen, The Netherlands

Definition

Digital filtering is the process of transforming a discretely sampled input signal into an output signal, such that certain spectral characteristics of the input signal are lost, while others are retained. In neuroscience, it is performed on time series that represent electrophysiological or hemodynamic signals measured over time. Whereas analog filters are applied online and implemented as electronic circuits, digital filters are applied off-line and implemented in software.

Detailed Description

Introduction

A digital filter is an important signal processing tool for the analysis of neuroscientific data. It is used to increase sensitivity to aspects of the signals that are of interest while suppressing noise. For the purpose of simplicity, we will focus on electrophysiological time series, e.g., temporal fluctuations of the electric potential measured at the scalp (for an extensive treatment of digital

filters see Smith 2003). Yet, a digital filter can be applied to any discrete signal sampled as a function of time, e.g., hemodynamic time series, but also to signals sampled across space such as an anatomical image obtained with magnetic resonance imaging (MRI). Typical applications of digital filters in computational neuroscience include the removal of (power-)line noise, high-pass filtering prior to rectification for the analysis of multiunit activity, and low-pass filtering for the reduction of high-frequency noise prior to event-related potential averaging.

A digital filter changes the shape of the input signal in a way that can be fully characterized by means of its impulse response. For practical purposes, however, it is more convenient to describe filter performance in terms of its frequency domain response.

Frequency Domain Performance

A filter is designed to keep certain spectral content and remove others. For example, a high-pass filter only passes spectral content from the input signal above a certain cutoff frequency, and a band-stop filter suppresses spectral content in a certain frequency band. A more detailed account of filter performance is given by the filter's amplitude and phase response as a function of frequency (Fig. 1a, b). This can be obtained by taking the discrete Fourier transform of the impulse response (Fig. 1c).

The ideal amplitude response would be a box-car function, indicating that the amplitude of the “pass” frequencies is unaffected and the amplitude of the “stop” frequencies is fully suppressed. In reality, however, the transition from passband to stopband is in general much more gradual, and the amount of attenuation in the stopband is variable. Figure 1a (blue) shows as an example the amplitude response of a 30 Hz low-pass filter, with a slow but deep roll-off. The filter in Fig. 1a (green) has a steep but oscillating roll-off. A filter can also have unwanted effects on the “pass” frequencies.

The phase response shows to what extent the phase of the oscillatory components in the input

Digital Filtering, Fig. 1 Example of two 30 Hz low-pass (forward) filters. (a–c) *blue lines* are the fourth-order IIR forward filter (Butterworth), and *green lines* are the 90th-order FIR forward filter (window method). (a) Amplitude response. Note the fast but oscillating roll-off of the FIR

filter (*green*) and the slow but deep roll-off of the IIR filter (*blue*). (b) Phase response. The FIR filter has a linear phase for the first part of the stopband. The IIR filter has a nonlinear phase throughout the stopband. (c) Impulse response

signal is affected by the filter. Filters that do not introduce a phase shift, i.e., the peaks of the oscillations in the output signal occur at the same time points as the peaks of the oscillations in the input signal, are called zero phase, or acausal filters. In contrast, nonzero phase or

causal filters introduce a phase shift, which can be either linear as a function of frequency (Fig. 1b, green) or nonlinear (Fig. 1b, blue). The desired phase response depends on the aim of the analysis step. In most cases a zero phase or acausal filter is desired.

Affecting the Amplitude Response

The amplitude response of a filter is determined mainly by the filter order. Filter order can be thought of as the “length” of the filter. It specifies how much time-domain information from the input signal is used to construct each sample of the output signal. The higher the filter order, the

better individual frequencies can be distinguished, thus leading to “faster” transitions in the amplitude response (also termed fast roll-off) (Fig. 2a, blue). In contrast, a low filter order results in a “slow” amplitude response (slow roll-off) (Fig. 2a, green). Additionally, the longer the impulse response, the further oscillatory components are time shifted in the output signal, i.e., the

Digital Filtering, Fig. 2 Example of a high and low order 30–60 Hz band-pass (forward) FIR filter. (a–c) *blue lines* are the 360th-order FIR forward filter (window method), and *green lines* are the 90th-order FIR forward filter (window method). (a) Amplitude response. The higher-

order filter shows a considerably quicker passband to stopband transition. Higher-order filters use more time-domain information and can thus more easily distinguish neighboring frequencies. (b) Phase response. (c) Impulse response

bigger the phase shift in the phase response (Fig. 2b). Note that there is always a trade-off between frequency and time resolution (Fig. 2c). A higher filter order trades time resolution for a sharper amplitude response.

Affecting the Phase Response

Typically the phase response is considered to be of less importance than the amplitude response. In applications where the phase of the oscillations is relevant, it should always be taken into account. Practically, any causal filter can be made acausal. This is achieved by filtering the input signal twice, in opposite directions. The phase shift introduced in the first filter step is “undone” by the filter applied to the signal in reverse (Fig. 3). These two steps are also called forward and backward filtering. Note that this bidirectional filtering attenuates all amplitudes twice as compared to unidirectional filtering.

Two Classes of Filters

Of the many types of filters that exist, two broad classes can be distinguished: (1) convolution, or finite impulse response (FIR) filters, and (2) recursive, or infinite impulse response (IIR) filters. FIR filters operate by convolution of the input signal with the filter coefficients. In short, the result of the convolution operation is that each sample in the output signal is constructed as a weighted sum of N samples of the input signal, where N represents the filter order and the weights are given by the filter coefficients. As a consequence the length of the impulse response is equal to the filter order, which gives the FIR filter its name. The filter coefficients can be constructed in various ways. A common approach is the “window method,” in which an ideal IIR filter is constructed and then truncated by a particular window function (such as a Hamming window) of N samples. Another approach is the “least squares method,” in which a filter of order N is found whose amplitude response is the least squares approximation of the desired amplitude response.

IIR filters operate in a different way. In this case each sample of the output signal is constructed from a weighted combination of N samples of the input signal and of $N-1$ previously obtained samples of the output signal. Because of this recursion, all previous samples in the input signal contribute to the output signal. The impulse response thus is infinitely long, which gives the IIR filter its name. Still, most of the energy of the impulse response is concentrated in a limited number of samples, the length of which depends on the filter order, the pass/stop frequencies, and their range. Commonly used IIR filters are Butterworth and Chebyshev filters.

Which class of filter is most optimal depends on the situation. In general FIR filters are preferred when temporal spread of the impulse response is undesired. An example would be band-pass filtering followed by a Hilbert transform to estimate temporal fluctuations in the amplitude and phase of band-limited signal components. In this case it is desired to have full control over the temporal information that is used to construct the filtered signal, because one would like to relate more or less precisely the “instantaneous” amplitude to the time point at which that amplitude occurred. The FIR filter order directly specifies the temporal information that is used. An IIR filter will only provide very indirect control of temporal spread and is therefore less ideal to use in this scenario. Note that FIR filter bandwidth must be sufficiently large for a well-behaved amplitude response. When the length of the impulse response is unimportant, IIR filters are often the preferred choice, as they are more computationally efficient than FIR filters. An example would be the suppression (power-)line noise. In this case it is irrelevant how much temporal information is used, as long as the noise is maximally suppressed. Temporal spread of the impulse response is important to keep in mind for other practical considerations such as edge artifacts (described in the next section).

Edge Artifacts

Apart from desired effects, a filter can also have undesired effects. A common one is an

Digital Filtering, Fig. 3 The effect of bidirectional filtering with a 30–60 Hz band-pass 90th-order FIR filter (window method). (a–c) *blue lines* represent filtering only in the forward direction, and *green lines* represent forward *and* reverse filtering. (a) Amplitude response. The bidirectional filter (*green*) has a much stronger amplitude attenuation of the stopband but also has a faster roll-off. (b) Phase response. The original forward filter shows a

considerable linear and nonlinear phase shift. The bidirectional filter, however, has zero phase, indicating that all of the phase shifting of the forward filter is reversed. (c) Impulse response. In this example, the impulse was centered at $t = 0$. Because the forward filter was causal, the impulse response occurs *after* $t = 0$. The bidirectional filter is acausal; however, the impulse response is centered *around* $t = 0$

edge artifact, from which all filters suffer. When filtering the beginning of a signal, the filter is not fully immersed in the data. Because only a part of the filter is used, the performance is very poor, resulting in “filter

ringing” at the edges (Fig. 4a, b). It takes an FIR filter at least N samples of the input signal to stabilize, where N is the filter order. For an IIR filter it is more complicated, as the other parameters play an equally important role. The

Digital Filtering, Fig. 4 Example of edge artifacts and their prevention. *Panel A* shows 1.5 s of example data with a strong 60 Hz line noise component on top of it. In order to remove this, a 59–61 Hz band-stop fourth-order bidirectional IIR filter (Butterworth) is used (*panel B*). However, at the edges of the signal, the filter is not fully immersed in

the data, causing residual 60 Hz noise to present. In order to remedy this, a larger data segment is filtered (200 ms data padding on each side; *panel C*; gray boxes). The edge artifacts now occur in the padded segments. After removal of the padded segments, the original 1.5 s of data is artifact-free

easiest solution to edge artifacts is data padding. By filtering a longer signal than required, the artifacts end up in the uninteresting parts of the signal, which can be cut off afterward (Fig. 4c). Other padding methods, like mirror/zero/mean padding, are less optimal, because these may introduce sharp transitions in the signal.

Directed Information Flow and Causality in Neural Systems

Michael C. Gastpar

Ecole Polytechnique Fédérale de Lausanne (EPFL), EPFL-IC-ISC-LINX, BC 106, Lausanne, Switzerland

Definition

In the human experience, information typically flows from one place to another. By contrast, the notion of mutual information introduced by Shannon (1948) is perfectly symmetric in its arguments and does not distinguish between “input” and “output.” In this sense, it is perhaps surprising that this very measure of information indeed captures the capacity of any communication channel – though we should recall that the proof of this fundamental fact is not merely a simple consequence of Shannon’s definition.

In spite of Shannon’s strong and fundamental results, it has been tempting to define a notion of *directed* information. This was first proposed in (Marko 1973) for stationary processes. The more general and useful definition was given in the brief and beautiful note by Massey (1990). Moreover, Massey (1990), Kramer (1998) and subsequent work revealed that directed information has a natural place in the study of information transmission with feedback from the output to the input.

In the present note, a different aspect of directed information is illuminated: that of identifying causal relationships. The basic idea is that if there is a causal relationship from one process to another, the directed information in the forward direction should be large. Additionally, one may also require the directed information in the reverse direction to be small.

It is important, however, to observe that inferring causality from observations is an ill-posed question. This has been discussed in depth in the context of Granger causality (Granger 1969), where a rich literature exposes several fundamental issues. The same qualitative issues apply to any causality argument based on directed information measures. The difference is that Granger causality uses correlation measures, whereas here, we consider directed information.

Detailed Description

Directed Information

The usual mutual information can be defined between any two random variables. For directed information, however, we need to consider *ordered sequences* of random variables.

Specifically, for two random sequences $X = (X_1, X_2, \dots, X_N)$ and $Y = (Y_1, Y_2, \dots, Y_N)$ of equal length N , the directed information is defined as

$$I(X \rightarrow Y) = \sum_{n=1}^N \{I(X_1, \dots, X_n; Y_1, \dots, Y_n) - I(X_1, \dots, X_n; Y_1, \dots, Y_{n-1})\},$$

where $I(\cdot;\cdot)$ denotes the regular Shannon mutual information. Let us first record that this is always nonnegative: $I(X \rightarrow Y) \geq 0$, which follows directly from the definition and the fact that Shannon mutual information is always nonnegative. Second, we note that the directed information is never larger than the regular Shannon mutual information between the two sequences.

Moreover, it is tempting to ask about the relationship between the forward directed information $I(X \rightarrow Y)$ and the reverse directed information $I(Y \rightarrow X)$. For general probabilistic models, there does not appear to be an intuitively pleasing connection between these two. However, if one considers instead the following new random sequence $\tilde{Y} = (0, Y_1, Y_2, \dots, Y_{N-1})$, then the following conservation law applies (Massey and Massey 2005):

$$I(X \rightarrow Y) + I(\tilde{Y} \rightarrow X) = I(X; Y), \quad (1)$$

where the latter denotes the regular Shannon mutual information between the two sequences X and Y .

To have a brief and simple example, let us consider the situation where $(X_1, X_2, \dots, X_N)$ are independent normal (Gaussian) random variables of mean zero and variance 1. Let Y_1 also be a mean-zero unit-variance normal. For $n \geq 2$, we set $Y_n = \alpha X_{n-1} + W_n$, where W_n are independent normal random variables of mean zero and variance $1 - \alpha^2$ and $0 \leq \alpha \leq 1$. Then, the directed information evaluates to

$$I(X \rightarrow Y) = \frac{N-1}{2} \log_2 \left(1 + \frac{\alpha^2}{1 - \alpha^2} \right). \quad (2)$$

In this example, the reverse directed information vanishes: $I(Y \rightarrow X) = 0$.

Finally, we also note that another 10 years later, directed information was again discovered (interestingly again with a stationarity assumption) under the name of transfer entropy (Schreiber 2000).

Directed Information in Networks

The concept of information flow requires that information cannot be created simply by processing a signal in a particular way. For mutual information, this is ensured by the data processing inequality, stating that the mutual information cannot be increased by further processing of the output signal. For directed information, the situation is a little more complex. Namely, a data processing inequality still applies but only to *causal* processing of the output signal. That is, if Z is a sequence obtained by processing the sequence Y in a causal fashion, possibly involving additional independent randomness, then we have that

$$I(X \rightarrow Z) \leq \min \{I(X \rightarrow Y), I(Y \rightarrow Z)\}. \quad (3)$$

As with all information measures, the reverse is not true. More precisely, let us reconsider the scenario just discussed involving the sequences X , Y , and Z . Then, even if both $I(X \rightarrow Y)$ and $I(Y \rightarrow Z)$ are large, this *does not* imply any lower bound on $I(X \rightarrow Z)$; in fact, the latter might even be zero.

Information Measure of Causality

Directed information can be postulated to be a measure of causality in the following sense: One claims a causal relationship from X to Y if the directed information $I(X \rightarrow Y)$ is large. In the explicit example involving normal random variables discussed above, this is easy to see: The directed information from X to Y is large, and indeed, for this example, we would expect any rationale to conclude that the sequence X drives the sequence Y in a causal fashion (at least as long as α is close to one). Moreover, in this example, $I(Y \rightarrow X) = 0$, ruling out any causal relationship in the reverse direction.

The remaining issue is to define a threshold on the directed information above which the relationship is claimed to be causal. There is no

intuitive a priori rule, and in most cases, the threshold must be selected arbitrarily or using additional knowledge of existing causal connections, e.g., from physiological insight into the considered connection. To make matters more complicated, it is also important to notice that due to the nonnegativity of directed information, most classical estimators must be expected to have a positive bias.

It should also be noted that this is closely related in spirit to the notion of Granger causality (Granger 1969). In the latter, *correlation* (i.e., second-order statistics) is exploited to claim causality. Directed information, by contrast, is sensitive to the full probability distribution in the usual entropy sense. Note that when directed information is considered with normal distributions, it is closely related to Granger causality.

Experimental Studies

Directed information measures have been recently applied to simultaneous recordings in the primary motor cortex of rodents and macaque monkeys (Quinn et al. 2011; So et al. 2012), leading to conjectured causality maps (directed graphs) between the observed neurons. An additional rich literature concerns the transfer entropy mentioned above, but is discussed elsewhere.

Directed Spectral Methods

Adam B. Barrett and Anil K. Seth
Sackler Centre for Consciousness Science and
Department of Informatics, University of Sussex,
Brighton, UK

Definition

Directed spectral measures quantify, in the frequency domain, directed statistical interactions between time-series variables. Most commonly, the various measures are computed based on a (linear) multivariate autoregressive (MVAR) model of the data. The various methods quantify in different ways the strength of interaction terms in the Fourier transform of the MVAR model. While these methods are sometimes referred to as capturing “causal” or “effective” connectivity, they are most properly described as reflecting “directed functional connectivity” (Friston et al. 2013).

Detailed Description

For a multivariate n -channel process $X(t) = [X_1(t), X_2(t), \dots, X_n(t)]^T$ (with zero mean), the MVAR model is given by:

$$\mathbf{X}(t) = \sum_{k=1}^p \mathbf{A}_k \cdot \mathbf{X}(t-k) + \epsilon(t), \quad (1)$$

where the $\mathbf{A}_k$ are matrices of regression coefficients, p is the model order, and $\epsilon(t)$ are the residuals (Lütkepohl 2007). The coefficients of this model are uniquely specified by imposing zero correlation between the residuals and the regressors $\mathbf{X}(t-k)$, $k = 1, \dots, p$, and can be derived from the Yule-Walker procedure (Ding et al. 2006). Ideally, the model order should be sufficiently high to obtain a good representation of the data, but not so high that overfitting and poor parameter estimation occur. Commonly the model order is selected based on minimizing either the Akaike Information Criterion or the Bayes Information Criterion, both of which balance the residual variance against the number of coefficients to be estimated (Ding et al. 2006).

Directed spectral measures are computed from the frequency domain representation of the MVAR model:

$$\mathbf{A}(\omega) \cdot \tilde{\mathbf{X}}(\omega) = \tilde{\epsilon}(\omega), \quad (2)$$

where explicitly in terms of the regression coefficients:

$$\mathbf{A}(\omega) = \mathbf{I} - \sum_{k=1}^p z^k \mathbf{A}_k, \quad (3)$$

$z = e^{-2i\pi\omega\Delta t}$ and Δt is the time between observations. (Let tildes denote Fourier transform and dagger the Hermitian conjugate.) The measures are written in terms of $\mathbf{A}(\omega)$, the spectral density (or power) $S(\omega) = \tilde{\mathbf{X}}(\omega) \cdot \tilde{\mathbf{X}}^\dagger(\omega)$, the covariance matrix of the residuals Σ , and also the transfer matrix $\mathbf{H}(\omega) =: \mathbf{A}^{-1}(\omega)$, which yields $\tilde{\mathbf{X}}(\omega)$ when it acts on the Fourier transformed residuals:

$$\tilde{\mathbf{X}}(\omega) = \mathbf{H}(\omega) \cdot \tilde{\epsilon}(\omega). \quad (4)$$

Nonparametric estimation. An alternative method for computing directed spectral measures involves obtaining the transfer matrix directly from

Fourier and wavelet transforms of the data, obviating the need to explicitly fit an MVAR model (Dhamala et al. 2008; Percival and Walden 2000). An advantage of this approach is that it bypasses the need for model order estimation; however, this is replaced with the task of choosing the wavelet prototype and number of tapers appropriately.

Granger-Geweke Causality (GGC)

For a pair of variables $\mathbf{X}(t) = [X_1(t), X_2(t)]^T$, the Granger-Geweke causality $\text{GGC}_{2 \rightarrow 1}(\omega)$ from X_2 to X_1 at frequency ω quantifies the directed contribution of X_2 to the power of X_1 at frequency ω (Ding et al. 2006; Geweke 1982). It does this by expressing the total power of X_1 as the sum of an “intrinsic” term and a “causal” term, and comparing the logarithms of the total power and the intrinsic power. From an MVAR model of the two variables, the power can be expressed via (4) as:

$$S(\omega) = \mathbf{H}(\omega) \cdot \Sigma \cdot \mathbf{H}^\dagger(\omega). \quad (5)$$

The decomposition of this into an intrinsic term and a causal term is obtained via the transformation of variables $X_2 \rightarrow X_2 - (\sigma_{21}/\sigma_{11})X_1$, which diagonalizes Σ and hence removes the cross-terms from the RHS. (Since GGC is interested in the independent causal contribution from X_2 to X_1 , it should by definition be invariant under the addition of a multiple of X_1 to X_2 .) After this transformation, we have:

$$S_{11}(\omega) = H_{11}(\omega)\sigma_{11}H_{11}^*(\omega) + H_{12}(\omega)\sigma_{22}H_{12}^*(\omega). \quad (6)$$

GGC is given (after the transformation) by:

$$\text{GGC}_{2 \rightarrow 1}(\omega) = \ln \left\{ \frac{S_{11}(\omega)}{H_{11}(\omega)\sigma_{11}H_{11}^*(\omega)} \right\}. \quad (7)$$

To analyze a system of n variables, one can compute the above pairwise GGC between each pair of variables by fitting MVAR models successively to each pair of variables. There also exists: (i) the more complicated $\text{GGC}_{j \rightarrow i | k_1, \dots, k_\ell}$, i.e., the conditional GGC from X_j to X_i conditional on

$X_{k_1}, \dots, X_{k_\ell}$ (Ding et al. 2006; Geweke 1984), which computes in the same fashion the causal contribution of X_j to the power of X_i that is independent of the causal contributions of $X_{k_1}, \dots, X_{k_\ell}$ to the power of X_i and the intrinsic power of X_i ; (ii) “multivariate GGC” from one group of variables to another group of variables (Barrett et al. 2010; Geweke 1982).

The spectral GGC is related to its time-domain formulation (Ding et al. 2006; Geweke 1982; Granger 1969). The time-domain GGC from X_2 to X_1 quantifies the extent to which the past of X_2 helps predict the future of X_1 over and above the extent to which the past of X_1 predicts its own future. Specifically, it is given by the logarithm of the ratio of the residual variance in a restricted regression of X_1 on its past to the residual variance σ_{11} in the (unrestricted) MVAR model of $[X_1, X_2]^T$. The mean spectral GGC over all frequencies up to the Nyquist frequency is equal to the corresponding time-domain GGC.

Partial Directed Coherence (PDC)

The partial directed coherence $PDC_{j \rightarrow i}(\omega)$ is defined as (Baccalá and Sameshima 2001):

$$PDC_{j \rightarrow i}(\omega) = \frac{A_{ij}(\omega)}{\sqrt{\sum_{k=1}^n |A_{kj}(\omega)|^2}}. \quad (8)$$

This measure represents the relative coupling strength of the interaction from X_j to X_i , as compared to all of X_j 's interactions as a source with other structures. The PDC ranks the relative interaction strengths with respect to a given signal source, and the normalization is such that:

$$0 \leq |PDC_{j \rightarrow i}(\omega)|^2 \leq 1, \quad (9)$$

$$\sum_{i=1}^n |PDC_{j \rightarrow i}(\omega)|^2 = 1. \quad (10)$$

Directed Transfer Function (DTF)

The directed transfer function $DTF_{j \rightarrow i}(\omega)$ is defined as (Kaminski and Blinowska 1991):

$$DTF_{j \rightarrow i}(\omega) = \frac{H_{ij}(\omega)}{\sqrt{\sum_{k=1}^n |H_{ik}(\omega)|^2}}. \quad (11)$$

This measure represents the coupling strength of the interaction from X_j to X_i , as compared to the sum of those from all variables to X_i . Similar to PDC, the normalization is such that:

$$0 \leq |DTF_{j \rightarrow i}(\omega)|^2 \leq 1, \quad (12)$$

$$\sum_{j=1}^n |DTF_{j \rightarrow i}(\omega)|^2 = 1. \quad (13)$$

Since it makes use of the inverse of the regression matrix, the DTF measure is a linear combination of direct and indirect couplings. The “direct DTF” (dDTF) variant is an alternative that emphasizes direct connections (Korzeniewska et al. 2003). Note that, unlike for GGC, there is no corresponding time-domain connectivity map for PDC or DTF.

Limitations and Extensions

Stationarity. These measures assume that the time-series are covariance stationary. Non-stationary data should be divided into windows that by themselves are approximately stationary (Seth et al. 2015). Moving average components can be dealt with by computing these measures on stationary hidden variables in a “state-space” model (Barnett and Seth 2015).

Dependence on variables. The measures reflect directed statistical dependencies among the particular set of variables chosen and should not be interpreted as directly reflecting physical causal chains.

Linearity. The linear formulation of these measures can obviously only give information about linear features of signals. Extension to non-linear cases can however present further problems. Marinazzo et al. (2011) review some nonlinear approaches to GGC. Note that for (stationary) Gaussian variables, interactions are necessarily linear, and time-domain GGC is equivalent to transfer entropy, enabling an interpretation of GGC in terms of Shannon information flow (Barnett et al. 2009; Barrett et al. 2010).

Neurobiological Application

The above limitations should always be kept in mind when applying these measures to neurobiological data. A general principle is that shorter data segments are more stationary than longer data segments but yield poorer parameter estimates. Thus a trade-off must be made in choosing the segment length; the most appropriate choice will depend on whether the data are “event-related” or “steady-state,” and on the estimated model order (Cohen 2014; Seth et al. 2015). Typically, segment lengths range from 500 to 2000 ms (Cohen 2014). These measures are applicable to continuous variables, and therefore to M/EEG or local field potential data, as opposed to spiking data. The sampling rate should be sufficiently high for the Nyquist frequency to be substantially greater than the highest frequency of interest, but not so high that the model order becomes too large (Barnett and Seth 2017); 200–250 Hz is typical (Cohen 2014). For M/EEG, preprocessing should include some form of spatial filtering or source localization in order to minimize volume conduction artifacts (Seth et al. 2015). Bandpass temporal filtering should be avoided as this smears the data in time and can increase model orders, thus leading to poorer estimates of the measures (although notch filtering to remove line-noise will not contaminate frequencies that are far away from the stop-band (Barnett and Seth 2011)). Application to fMRI is problematic due to the combination of slow sampling rate and the measuring of smeared neurodynamics, in the form of hemodynamics, although research into this is ongoing (Barnett and Seth 2017). The freely available “Multivariate Granger causality toolbox” (Barnett and Seth 2014) can facilitate application of GGC.

Summary and Comparison of Measures

$\text{GGC}_j \rightarrow i$ is a measure of the directed functional effect that X_j has on X_i and compares “intrinsic” and “causal” contributions to the power in a bivariate autoregressive model (conditional versions of GGC are used if one wants to separate out direct and indirect causal effects). $\text{PDC}_j \rightarrow i$

captures the relative strength of the direct pairwise coupling from X_j to X_i , compared to the total coupling from X_j to other variables in the frequency domain MVAR model for the set of variables. $\text{DTF}_j \rightarrow i$ compares the coupling from X_j to X_i with the total coupling from all variables to X_i in the transfer matrix for the set of variables; as such it is a measure of the combined strength of direct and indirect couplings from X_j to X_i . These measures, of which GGC is the most common and perhaps best founded, hold great promise in moving beyond functional localization towards the important problem of dissecting the functional circuits underlying cognition, perception, and behavior.

[Liley model](#); [Robinson model](#); [Steyn-Ross model](#)

Definition

Australia and New Zealand, despite their relatively small academic communities, have been vibrant sites for the development and application of a number of important approaches to the mesoscopic modeling of neural populations, developed initially to account for the physiological genesis of rhythmic activity in the mammalian electroencephalogram. These models are collectively referred to as “down under” neural population models.

Detailed Description

History

The work of Wright (Wright and Kydd 1984), which aimed theoretically to account for the regulatory effects of lateral hypothalamic activity on electrocortical activity, can be seen as the progenitor of the later “down under” models that were developed to account for electrocortical rhythmogenesis. In this approach telencephalon was functionally modeled as a mass of coupled linear oscillators. While largely phenomenological and not formulated in terms of the structure and composition of cortical tissue, this theory nevertheless gave mathematical form to the role that a specific anatomical pathway played in modulating electroencephalographic activity. The ambitions of Wright’s approach significantly influenced the subsequent development of a number of neural population models.

Primary Models

Three principal neural population models form the core of “down under” approaches. The population model of Robinson et al. (1997) considered the propagation of axonal pulse activity in continuously distributed planar cortical populations of excitatory and inhibitory neurons and was later extended to include thalamocortical feedback (Robinson et al. 2002). The model of Liley et al. (1999, 2002), which also theoretically incorporated spatially continuous axonal pulse propagation, focused on the topology of intracortical and cortico-cortical connectivity and differentiating the kinetics of excitatory and inhibitory neurotransmission. Finally Steyn-Ross et al. (2007) developed an approach based on Liley et al. (1999, 2002) that included the effects of electrical gap junction synapses. All models represent examples of continuum neural field models (see entries ► “Neural Field Model, Continuum”; ► “Neural Population Model”).

Robinson et al.: Thalamocortical Feedback

The model of Robinson et al. (2002) originally described cortical activity in terms of a spatially

homogeneous field quantity ϕ_e (propagated excitatory neuronal pulse rate) evolving according to the following set of *delay ordinary differential* equations:

$$\left. \begin{aligned} L_{ax} \phi_e(t) &= S[V_e(t)], \\ L_{dend} V_e(t) &= a_{ee} \phi_e(t) + a_{ei} S[V_e(t)] + a_{es} S[V_s(t - T/2)], \end{aligned} \right\} \text{cortex} \quad (1)$$

$$\left. \begin{aligned} L_{dend} V_r(t) &= a_{re} \phi_e(t - T/2) + a_{rs} S[V_s(t)], \\ L_{dend} V_s(t) &= a_{se} \phi_e(t - T/2) + a_{sr} S[V_r(t)] + a_{sn} \phi_n(t), \end{aligned} \right\} \text{thalamus} \quad (2)$$

where e, i, r, s index, respectively, cortical excitatory, cortical inhibitory, thalamic reticular, and thalamic relay neuronal populations, a_{jk} nominally represent population synaptic weights, V_l represents a mean population membrane potential, S a sigmoidal firing rate function, τ a fixed delay, and ϕ_n an external pulse input. The fixed delay τ represents the return corticothalamic conduction time. L_{ax}, L_{dend} define *second-order* linear ordinary differential operators that account for passive neuronal population cable delays and pulse propagation via cortico-cortical fibers, respectively:

$$\begin{aligned} L_{ax} &= \frac{l^2}{v^2} \frac{d^2}{dt^2} + 2 \frac{1}{v} \frac{d}{dt} + 1; L_{dend} \\ &= \frac{1}{\alpha\beta} \frac{d^2}{dt^2} + \left(\frac{1}{\alpha} + \frac{1}{\beta} \right) \frac{d}{dt} + 1, \end{aligned} \quad (3)$$

where l is the mean range of excitatory axons of velocity v . This model was subsequently generalized to the spatially inhomogeneous case (Robinson et al. 2004). This model has been used to investigate the genesis of the resting alpha rhythm, the dynamical instability of epilepsy, and the oscillatory architecture of sleep.

Liley et al.: Kinetics of Excitatory and Inhibitory Neurotransmission

The neuronal population formulation of Liley et al. (2002) is an example of a conductance-based model. The defining equations distinguish between the kinetics of excitatory and inhibitory neurotransmission and the topology and properties of intracortical and cortico-cortical

connectivity. It describes cortical activity in terms of the mean soma membrane potential $h_k(r, t)$ of spatially continuously distributed cortical populations of excitatory ($k = e$) and inhibitory ($k = i$) neurons:

$$T_k \partial_t h_k(r, t) = h_k^{\text{rest}} - h_k(r, t) + \sum_l \psi_l [h_k(r, t)] I_{lk}(r, t), \quad (4)$$

$$(\partial_t + \gamma_{lk})^2 I_{lk}(r, t) = \exp(1) \gamma_{lk} \Gamma_{lk} \left\{ N_{lk}^\beta S_l [h_l(r, t)] + \phi_{lk} + p_{lk}(t) \right\}, \quad (5)$$

$$(\partial_t + v_{ek} A_{ek})^2 \phi_{ek}(r, t) + \frac{3}{2} v_{ek}^2 \nabla^2 \phi_{ek}(r, t) = N_{ek}^\alpha v_{ek}^2 A_{ek}^2 S_e [h_e(r, t)], \quad (6)$$

$$\phi_{ik}(r, t) = 0, \quad (7)$$

where $r \equiv (x, y)$, τ_k is a membrane time constant and $\psi_l [h_k(r, t)]$ incorporates the effect of the reversal potential on the respective postsynaptic potential of type l . ∂_t and ∇^2 are the temporal derivative and 2D Laplacian operator, respectively. The amplitude and characteristic timescale of the unitary postsynaptic potential of type l are given by Γ_{lk} and γ_{lk} , respectively. The topology of neuronal population connectivity is defined in terms of the intracortical (N_{lk}^β) and cortico-cortical (N_{lk}^α) connectivity between a presynaptic population l and a postsynaptic population k . Cortico-cortical connectivity is assumed to exclusively propagate pulses via axons of excitatory neurons having a conduction velocity v_{lk} and a characteristic length l/A_{lk} . This model has been utilized to account for the emergence of the resting EEG spectrum and its perturbation during anesthesia.

Steyn-Ross et al.: Electrical Gap Junctions

In a novel departure from the usual axo-synaptic connectivity of most neural population models,

Steyn-Ross et al. (2007), on the basis of substantial empirical evidence, added the bulk effects of gap junction currents. Gap junctions are intercellular protein channels that can form spontaneously at the point of contact between the dendritic trees of two adjacent neurons and enable the free diffusion of ions (current) along intercellular electrochemical gradients. By assuming homogeneous cellular ionic environments, such free diffusion will be determined by intercellular potential differences. On this basis Steyn-Ross et al. (2007) defined the mean soma membrane potential $h_k(r, t)$ of a spatially continuously distributed cortical neuronal population of type k in terms of a modified conductance-based neuron:

$$T_k \partial_t h_k(r, t) = h_k^{\text{rest}} - h_k(r, t) + \sum_l \psi_l [h_k(r, t)] I_{lk}(r, t) + D_{kk} \nabla^2 h_k(r, t) \quad (8)$$

where D_{kk} is a diffusive coupling strength between adjacent neurons of type k . The remaining equations defining the model are similar to that of Liley (see above). In general, because the density of gap junction coupling between inhibitory neurons is much greater than excitatory neurons, $D_{ii} \gg D_{ee}$. All other symbols are defined as before. This model has been invoked to account for the low-frequency oscillations seen in resting-state functional MRI.

Definition

Dynamic causal models with neural populations are state-space models that impose a specified dynamical systems form to the generation of neuroimaging and electrophysiological data. The forms of these models constitute neurobiologically motivated and identifiable parameterizations, where empirical observations offer conditional descriptions of parameter space following application of a Bayesian inversion scheme. They comprise separate generative processes at the neuronal level and at the observation level through a set of deterministic or stochastic differential equations and an observer functional, respectively.

Detailed Description

Dynamic causal models were first invented in 2003 for the purpose of estimating human brain connectivity and task-dependent functional integration using functional magnetic resonance imaging (fMRI) (Friston et al. 2003). The framework was extended for electrophysiological domains including non-invasive electroencephalography (EEG) and magnetoencephalography (MEG) and later for invasive local field potential recordings. Application domains share a common generative and inversion framework (Stephan et al. 2010). At the neuronal level, a network of “nodes” are connected with intrinsic (within-region) and extrinsic (region-to-region) connections.

These effective or model-based connections constrain the output of a set of differential equations and can be modulated by experimental perturbation. These are modality-dependent, mesoscale descriptions of neuronal ensemble activity and are summarized through mean-field reductions. Different connectivity architectures can be considered as different models, embodying competing hypotheses to be formally tested. At the observation level, contributing neuronal states form inputs to a second dynamic process or static function (lead field), transforming neuronal activity to the required measurement space, e.g., blood oxygen level dependent – BOLD fMRI responses. Together, these form a complete forward model that is inverted, given real data, using Bayesian approaches.

Modality-Dependent Population Models

The neural population model describes the time evolution of unobservable neuronal states. For fMRI, $\mathbf{x}$ is an $n \times 1$ column vector representing neuronal activity at n brain regions. This activity is under the control of inhibitory rate parameters, $a_{ij} \forall j = i$, describing the influence of regional activation on its own output activity and the excitatory or inhibitory influence, $a_{ij} \forall j \neq i$, from other brain regions. This $n \times n$ matrix A is referred to as the endogenous or intrinsic connectivity matrix. A bilinear approximation $B^{(j)}$ is an $n \times n$ matrix used to capture effects from m , experimental input modulations, and C , an $n \times k$ matrix, represents the direct perturbation from k experimental inputs, giving

$$\dot{\mathbf{x}} = \left(A + \sum_{j=1}^m u_j B^{(j)} \right) \mathbf{x} + C \mathbf{u} \quad (1)$$

Here, each state is a one-dimensional neural mass model representing the mean neuronal activity within a region encompassing approximately 10–100 voxels. Such a mean-field reduction is also applied to electrophysiological modalities where multiple-state models are used to represent several dimensions of unobservable dynamics within a single brain region (e.g., membrane depolarization changes at different inhibitory and

excitatory cell ensembles), owing to their higher temporal resolution. For example, DCM for EEG employs (among other models) the Jansen and Rit formulation (Jansen and Rit 1995) to describe layer-specific synaptic responses, where inputs, u , are convolved with postsynaptic kernels, h , which can depolarize (e) or hyperpolarize (i) the postsynaptic neuronal ensemble to produce an average membrane potential, v :

$$\begin{aligned} v &= h_{e/i} \otimes u \\ h_{e/i} &= H_{e/i} \kappa_{e/i} t \exp(-t \kappa_{e/i}) \end{aligned} \quad (2)$$

The parameter H tunes the maximum amplitude of PSPs and κ is a lumped representation of the sum of the rate constants of passive membrane and other spatially distributed delays in the dendritic tree. The convolution leads to a second-order differential equation (David and Friston 2003) that can be decomposed into normal form as

$$\begin{aligned} v(t) &= i(t) \\ i(t) &= H_{e/i} \kappa_{e/i} u(t) - 2\kappa_{e/i} x(t) - \kappa_{e/i}^2 v(t) \end{aligned} \quad (3)$$

A sigmoidal operator, S , then transforms the average membrane potential into a population firing rate and allows us to substitute direct (thalamic) input, u , with afferent input from other cell populations. These inputs are parameterized with a connectivity parameter γ and can arise from within the local layered neural mass or from pyramidal cells of other connected brain regions (both having identical mathematical form), giving, for example,

$$\begin{aligned} v &= i \\ i &= \kappa_e H_e (\gamma S(v_{\text{aff}}) + u) - 2\kappa_e i - \kappa_e^2 v \end{aligned} \quad (4)$$

Modality-Dependent Observers

Feature extraction from these neural population models is specified through an appropriate transform from the neural state space to measurement space. In the case of fMRI, this transform can be parameterized by a nonlinear “balloon model” (Buxton et al. 1998) describing the neuronal activity-induced dynamic alterations in vasodilation, blood flow, and subsequent volume and

deoxyhemoglobin content – to predict the observed BOLD time series. For electrophysiological modalities, a static lead field transforms a mixture of cell membrane potentials from each source to scalp-level-evoked, scalp-level-induced, or correlational data features (Kiebel et al. 2006):

$$h = L.Kx \quad (5)$$

where K describes the contribution from different cell ensemble potentials x , which is used to weigh, primarily, pyramidal cell contributions, and L is a lead-field matrix that accounts for passive conduction of their electromagnetic field and can be constrained along three orthogonal dimensions, when dipole orientations are not known.

Together with the neuronal state space, these transforms produce a full generative model with which mechanistic hypotheses regarding the physiological processes underlying empirical data observations can be performed.

Bayesian Inversion, Parameter Estimation, and Model Selection

The models described above produce the data likelihood and when combined with a set of priors on parameter space allow for a full Bayesian inversion. The inversions employed in DCM mostly use a variational expectation maximization routine (Šmídl and Quinn 2006) (stochastic routines employ generalized filtering). Here, a partition between the multivariate Gaussian model parameter space and the observation noise parameter (known as the hyperparameter) provides a scheme over which gradient ascent on a free energy objective function is amenable:

$$\begin{aligned} F &= \ln .25 \text{emp}(y|m) \\ &= KL(q(\theta) \parallel p(\theta|y, m)) \end{aligned} \quad (6)$$

This quantity F thence returns an approximation to the model evidence, which is exact for linear models as well as an approximate conditional parameter density q . These two quantities can then be used to assess competing model architectures

and the particular conditional (data: y , dependent) distributions on parameters, respectively.

Applications of DCM

The DCM approach has been applied to many experimental preparations and imaging modalities (a PubMed search reveals ~400 articles associated with dynamic causal modeling). As well as offering insights into the fundamental role of effective brain connections, e.g., how callosal connections support interhemispheric integration in a task-dependent manner (Stephan et al. 2005) or how feedback loops are necessary to support prototypical event-related potentials (Garrido et al. 2007), specific network topologies have been elucidated for cognitive and motor phenomena in health and disease. DCM for fMRI was used in one study to ascertain which regions in a prefrontal-subcortical network drive the so-called “status quo” motor-bias behavior (Fleming et al. 2010), finding a prefrontal-causality the most likely. During learning, similar networks have been shown to adapt along bottom-up axes, with changes in connections that support motor responsivity driven by modulation from subcortical structures (den Ouden et al. 2010). In disease, support for disconnection-related mechanisms has been observed in patients with schizophrenia (Dima et al. 2009) but also in neurological disorders more traditionally associated with focal lesions, such as Parkinson’s disease (Marreiros et al. 2012). As a “mathematical microscope,” electrophysiological DCMs have been applied to small, one-node networks to uncover particular synapses and receptors subtending memory performance (Moran et al. 2011). Overall, the methodology provides a principled Bayesian framework to address the mechanisms of functional brain architectures that support our mental repertoire.

Dynamic Clamp Technique

Thomas Nowotny¹ and Pablo Varona²

¹Centre for Computational Neuroscience and Robotics, School of Engineering and Informatics, University of Sussex, Falmer, Brighton, UK

²Departamento de Ingenieria Informatica, Universidad Autónoma de Madrid, Madrid, Spain

Definition

Dynamic clamp is an electrophysiological technique for introducing simulated electrical components into biological cells using a real-time closed loop between the cell and a computer or another electronic device. Classic dynamic clamp protocols build a voltage-dependent current injection cycle to implement artificial membrane or synaptic conductances in the cell membrane of biological neurons. These protocols are employed to assess a large variety of neuronal computational

properties and are widely applied for studying the physiology of neural systems at the cellular and circuit levels.

Detailed Description

History

The use of closed-loop feedback interactions with living neurons for observation and control purposes goes back to the beginnings of electrophysiology when the voltage clamp technique was developed (Marmont 1949; Cole 1955). The voltage clamp technique measures currents across the membrane of excitable cells while holding the membrane potential at a constant level. In current clamp, on the other hand, the current passing into and out of the neuron is tightly controlled, while the membrane potential is being recorded. Both voltage and current clamp protocols are routinely used to study the electrical properties of neuronal membranes and contribute to the design of conductance-based neuron models. In the early 1990s, the first hybrid circuit experiments coupling living and artificial cells through synthetic electrical connections were carried out in heart cells (Tan and Joyner 1990) and neurons (Yarom 1991).

In 1992, Sharp et al. and Robinson and Kawai independently developed the dynamic clamp concept (Sharp et al. 1993; Robinson and Kawai 1993). The dynamic clamp technique operates in a real-time closed-loop manner: an intracellular electrode measures the membrane potential of a neuron, which is fed into a computer or an electronic device that calculates a current to inject into a postsynaptic neuron. The injected current is computed after solving a model that represents ionic or synaptic conductances or simulates the dynamics of individual neurons or neural networks. The postsynaptic cell can be identical to or different from the one from which the membrane potential is being recorded. This activity-dependent closed loop is repeated indefinitely and has to be implemented at a high enough frequency to achieve a realistic effect. Figure 1 illustrates a typical dynamic clamp configuration.

Applications and Implementations

The dynamic clamp technology for in vitro and in vivo electrophysiology has produced many examples of successful closed-loop interactions with neural systems, which include adding or cancelling ionic channels, adding or cancelling electrical or chemical synapses (including learning and plasticity protocols), and implementing hybrid circuits of real and artificial neurons and networks (for reviews see Prinz et al. (2004), Goaillard and Marder (2006), Destexhe and Bal (2009), and Economo et al. (2010)).

Different dynamic clamp software implementations have increasingly become available under both Windows (Pinto et al. 2001; Kullmann et al. 2004; Nowotny et al. 2006; Kemenes et al. 2011) and real-time Linux operating systems (Butera et al. 2001; Dorval et al. 2001; Muniz et al. 2009; Lin et al. 2010) and contribute to expand the use of dynamic clamp protocols by implementing a realistic cycle update in soft or hard real-time approaches. Novel active electrode compensation techniques also allow experimenters to conduct dynamic clamp experiments with a single high-resistance electrode (Brette et al. 2008; Samu et al. 2012).

Modern Developments

The dynamic clamp technique has been generalized in the context of activity-dependent stimulation protocols beyond electrophysiological input/output by using chemical and mechanical stimulation and optical recording methods (Chamorro et al. 2012). Dynamic clamp-inspired closed loops can also be used in novel assisted neurofeedback techniques by implementing goal-driven stimuli that not only depend on instantaneous measurements but also on an adequately long history of the recordings (Wallach et al. 2011; Chamorro et al. 2012; Fernandez-Vargas et al. 2013). Dynamic clamp and novel activity-dependent stimulation techniques reveal neural dynamics otherwise hidden under traditional stimulus–response protocols, provide control of regular and pathological states, induce learning processes, bridge between distinct

Dynamic Clamp Technique, Fig. 1 Typical dynamic clamp configuration. A cell is impaled by two electrodes, one for monitoring the membrane potential and one for injecting currents. The signal from the recording electrode is amplified, converted to a digital signal, and fed into the dynamic clamp software. The software calculates the appropriate current according to the model that is

simulated and issues a current command that is converted to an analog command and injected as a current through the current injection electrode. This cycle is repeated at a high frequency on the order of kHz. A second recording computer is often used to obtain an unbiased record of the experiment

levels of analysis, and lead to a further automation of experiments in neuroscience research.

Dynamic Diseases of the Brain

Gerold Baier¹ and John Milton²

¹Cell and Developmental Biology, Faculty of Life Sciences, University College London, London, UK

²W.M. Keck Science Center, The Claremont Colleges, Claremont, CA, USA

Synonyms

[Dynamical diseases](#); [Periodic diseases](#)

Definition

A *dynamic disease* of the nervous system is a disease that arises from abnormalities in neural control mechanisms. Whereas traditional approaches for classifying neurological diseases are based on (static) anatomical, cellular, and molecular abnormalities, the focus here is on

dynamics, namely the variation of signs and symptoms of disease as a function of time. The hallmarks of dynamic diseases are sudden, qualitative changes in the temporal pattern of clinical signs. Identifying a neurological disorder as a dynamic disease has two major implications: (1) the observed dynamics and their responses to various manipulations provide important insights into the nature and abnormality of neural control and (2) based on computational models of the abnormalities, it may be possible to devise novel treatment strategies for dynamic diseases of the brain.

Detailed Description

Historical Perspectives

The concept of a dynamic disease arises out of the concept of a *dynamical disease* introduced by Uwe an der Heiden, Leon Glass, Michael C Mackey, and their coworkers (Mackey and Glass 1977; Glass and Mackey 1979, 1988; Mackey and Heiden 1984; Bélair et al. 1995). A dynamical disease was defined as a disease that occurs in a normal feedback control mechanism operating in a range of parameters that produced qualitatively altered and presumably unhealthy, dynamical behaviors. The concept was illustrated by applications to the respiratory and hematopoietic systems where the onset of disease was marked by a change involving an oscillatory physiological pattern: in Cheyne–Stokes respiration, a regular breathing transforms to a periodically modulated breathing pattern; and in periodic chronic myelogenous leukemia, a normally constant level of leukocytes switched first to a periodically and then to a chaotically varying level. In each case, the qualitative changes associated with the onset of disease were explained via an analogous transition in the dynamics of a mathematical model of an underlying feedback control mechanism. Since time delays are essential components of feedback controllers, the models took the form of delay differential equations (see chapter ► [“Time-Delayed Neural Networks: Stability and Oscillations”](#)). To induce the transition in the models, only quantitative changes of parameters

were required. The changes in dynamics arose when the parameter values crossed so-called stability boundaries, corresponding mathematically to *bifurcations*. It was hypothesized that pathological oscillations in the selected diseases arose because normal physiological control mechanisms were operating in an abnormal parameter range. A consequence of the computational studies is that the understanding of the mechanism can lead to the prediction of novel treatments: in the case of a rare hematological disease, cyclic neutropenia, the oscillations in neutrophils can be stopped by the administration of granulocyte colony stimulating factor (G-CSF) (Foley and Mackey 2009), an intervention resulting in a bifurcation (specifically, a reverse Hopf bifurcation).

However, changes in dynamics can have various origins and are not necessarily associated with bifurcations. This is especially true in the nervous system in which sudden changes in neural dynamics can arise because of the responses of multistable neural networks to perturbations, the transient synchronization of neural population activity, the formation of traveling waves of electrical potential, and the response to random fluctuations in the vicinity of critical phenomena such as phase transitions. The more inclusive term dynamic disease includes all disorders characterized by abnormal dynamical behaviors. Thus, for example, epileptic seizures are the manifestations of a dynamic disease (Milton and Black 1995; Milton and Jung 2003) where features other than bifurcations have been proposed as underlying mechanisms.

In retrospect, it is surprising that diseases of the nervous system received only scant mention in early discussions of the dynamics of diseases (Glass and Mackey 1979, 1988; Mackey and an der Heiden 1984; Mackey and Milton 1987). Abnormal dynamical behaviors are frequently associated with diseases of the nervous system (Milton and Black 1995; Erdi et al. 2017) and characterize, for example, disorders of movement (e.g., tremors, Parkinsonism), mood (e.g., affective and psychotic disorders), and

consciousness (e.g., epilepsy, migraines, sleep-wake cycles). The large number of articles in this encyclopedia that address the computational aspects of disease attest to the importance of adopting a dynamical perspective in order to understand and treat dynamic diseases of the nervous system. Here we focus on a number of challenges and unsettled issues that concern the application of computational modeling to clinical practice. Our discussion of dynamical disease states is along a similar vein that Izhikevich has made for the mathematical classification of neuronal bursting patterns (Izhikevich 2007). Namely, an understanding of the basic mathematical mechanisms is mandatory to properly analyze the computational studies and to use these studies for the interpretation of clinical recordings of human brain activity. We therefore introduce a basic mathematical classification of transition between dynamic states and give examples where these concepts have been applied to disease states of the human brain. Finally, we discuss the unresolved computational challenges for the modeling of dynamic diseases of the nervous system and the development of novel, dynamically inspired treatment strategies.

Dynamical Transitions

We first restrict the discussion to qualitative changes in the temporal dynamics of some physiological variable. Taking the simplest case where there is the sudden appearance or disappearance of an oscillatory state, there are four major mathematical concepts that can explain this observation (Baier et al. 2012) (Fig. 1): (1) bifurcation; (2) bistability; (3) excitability; and (4) spontaneous bursting behavior (intermittency). These are illustrated in Fig. 1.

Bifurcation (Fig. 1a): A quantitative parameter change results in transition from one dynamic state to a qualitatively new state. The new state persists as long as the parameter value remains altered. Both states are robust to noise perturbations.

Bistability (Fig. 1b): Two qualitatively different states coexist under the same conditions (same

D

Dynamic Diseases of the Brain, Fig. 1 State transitions in dynamical systems as a function of control parameter. (a) In a monostable system, a transition is induced when a parameter crosses a bifurcation point. (b) In a bistable system, a suprathreshold stimulus (e.g., a short change of parameter) is required for each state transition. (c) In an

excitable system, a suprathreshold stimulus is required only to induce the first transition. The return to the original state is spontaneous. (d) In a system which exhibits spontaneous bursting behavior (deterministic intermittency), the transitions do not require change of parameter or external input to occur. (Reproduced from Baier et al. 2012)

parameter values). Transitions into and out of the abnormal state are realized via perturbations that are strong enough to cross the boundary separating the two states (the separatrix). Both states are vulnerable to noise perturbations.

Excitability (Fig. 1c): A stable state is interrupted temporarily by a qualitatively different abnormal state due to a suprathreshold perturbation. Both states are vulnerable to noise perturbations, but the return to the original state is spontaneous (i.e., does not require perturbation). Therefore, the abnormal state is only a transient.

Note that in principle, the transient can be arbitrarily complex.

Spontaneous bursting behavior (Fig. 1d): This globally stable state consists of two qualitatively different substates that alternate spontaneously, irregularly, and last for irregular periods of time. Consequently, both normal and abnormal dynamics are part of the overall state. Mathematically, this is equivalent to the type of dynamics called intermittency. However, whereas most of the mathematical literature on intermittency deals with low-dimensional models, actual brain

dynamics will more generally display spatiotemporal intermittency which at present is only incompletely understood.

This is the basic classification assuming that there is only one well-defined normal state. However, an organism can also transit from one state to another normal state, both characterized by different dynamics (e.g., during development or when transiting from sleep to the awake state). Pathological dynamics can then also occur (transiently) during the transition between two normal states (Milton et al. 2017) and see chapter ► “[Delay-Induced Transient Oscillation \(DITO\) and Metastable Behavior](#)”). The classification of such transitions is presently incomplete, but we will discuss an example below. We assume that such classification will necessarily involve advanced multivariate data analysis and will benefit from machine learning techniques as in the case of abnormally intermittent activity related to newborn and early childhood epileptic encephalopathies (Rosch et al. 2017).

Finally, the basic classification looks exclusively at temporal changes, whereas brain dynamics involves spatiotemporal changes of (neuro-) physiological variables. The theory of spatiotemporal systems again allows for more complex pathodynamics but is presently incomplete and will be illustrated only via example below.

Pathodynamics in the Human Brain

In order to illustrate dynamic disease approaches to neurological disease, we focus our discussion on epileptic seizures (see chapters ► “[Epilepsy: Computational Models](#),” ► “[Epilepsy: Abnormal Ion Channels](#),” ► “[Epilepsy, Neural Population Models of](#),” and ► “[Slow Oscillations and Epilepsy: Network Models](#)”). Topologically, seizures are characterized by their mode of onset. The term *focal* or *focal onset* is used to indicate a seizure which begins in a localized area of the brain. Focal or focal onset seizures are termed *simple* if there is no alteration in consciousness and *complex* if there is an alteration in consciousness. Traditionally, generalized seizures were distinguished between those that were generalized from the onset (primary generalized) and those that were the result of spread from an epileptic focus

(secondarily generalized). However, it is now clear that even in the primary generalized epilepsies, such as childhood absence epilepsy, there is a focal onset to the seizure (Gupta et al. 2011; Tenney et al. 2013; Westmijne et al. 2009). Thus the distinctions between primary and secondary generalization refer to the mechanism and pathways by which the seizure generalizes (Milton and Jung 2003). Dynamically, seizures are characterized by the sudden onset of an uncontrolled discharge pattern in very large populations of neurons and the diagnosis of epilepsy depends (in addition to the clinical history and description of the seizures) on the qualitative electroencephalographic (EEG) changes associated with seizures. Epilepsy, with its recurrent seizures, can therefore serve as the epitome of a dynamic disease.

Bifurcations

It is well established at the benchtop that dynamical transitions occur in neurons and simple neural circuits in which identified parameters have been changed systematically (Izhikevich 2007; Gerstner and Kistler 2002; Wilson 1999; Jirsa et al. 2014). The changes of neural activity here correspond to bifurcations in the appropriate mathematical models. In the context of brain disease, it has been difficult to demonstrate this phenomenon convincingly (Milanowski and Suffczynski 2016). There are two problems: (1) the relevant control parameter(s) cannot be directly identified from the observation of a dynamic transition and (2) the bifurcations exhibited in neural networks may be more complex (Jirsa et al. 2014; El Houssaini et al. 2015; Yang and Robinson 2017), a reflection of the possibility that seizures are generated by spatially extended epileptic systems (Milton et al. 2009; Eissa et al. 2017; Jirsa et al. 2017). Indirect evidence can be used in computational studies to argue for certain parameter changes and corresponding bifurcation patterns with some plausibility. The indirect evidence comes in various forms, for instance, by studying the phenomenology of waveforms (Ebersole and Milton 2003); by doing systematic parameter scan and sensitivity analysis; and by comparison with

experimental results from animal models of a specific disease.

The evolution of complex focal epileptic seizures has been considered to be an example where different states arise through transitions via bifurcations (Lopes da Silva et al. 2002). Analysis of clinical data from subdural and depth electrode recordings identifies a number of abnormal states characterized by distinct rhythmic properties: frequency, amplitude, and waveform. One model of focal seizures proposed by Wendling et al. is based on the mean behavior of large neural populations of principal and inhibitory neurons in the cortex (Wendling et al. 2002). A study of the generic bifurcation structure of this model identifies potential transition points where the dynamics change from background to pre-seizure, seizure, and post-seizure activity in accordance with the clinical data. Interestingly, the exploration of the model leads the authors to identify dynamics corresponding to a significant proportion of the highly heterogeneous rhythms during focal complex seizures with hippocampal origin. The computational study thus supports the hypothesis that patients with focal seizures share the basic neural circuitry but vary in the settings of their individual parameters. The model also explains how abnormal epileptic activity results from the unbalanced cooperation between excitatory and inhibitory neural populations. The major insight from the computational study is that focal-onset seizures tend to follow a certain route in parameter space during the course of the seizure (Wendling et al. 2005).

Bistability

As is the case for bifurcations, it is well established that neurons (Tasaki 1959; Guttman et al. 1980) and simple neural circuits (Foss et al. 1997; Foss and Milton 2000; Kleinfeld et al. 1990; Ma and Wu 2007) can exhibit bistability. It is to be expected that similar phenomena also occur on the level of the brain in vivo. Physicians have known for a long time that it is sometimes possible to abort pathological dynamics like cardiac arrhythmia or an epileptic seizure using a brief mechanical, electrical, or sensory stimulus (Lopes da Silva et al. 1994, 2002; Milton 2000;

Milton and Foss 1997; Rajna and Lona 1989). This points to the possibility that a seizure state coexists with a normal brain state and can be reached and left via specific perturbations (c.f. Fig. 1b). The likelihood of causing a switch between coexisting attractors by choosing the magnitude and timing of the stimulus randomly is very low (see chapter ► “Multistability: Stopping Events with Single Pulses”). Thus a great deal of attention has been focused on determining the basin of attraction of the normal state (Lopes da Silva et al. 2003; Zakyntinaki et al. 2010), that is, the set of state variables that will result in normal behavior. Noise-induced transitions across the separatrix (additive noise) provide another possible mechanism for epilepsy in the setting of bistability since they can be accompanied by the occurrence of delay-induced transient oscillations (see chapter ► “Delay-Induced Transient Oscillation (DITO) and Metastable Behavior”). Delay-induced transient oscillations may be related to the tendency of seizures in patients with nocturnal frontal lobe epilepsy to occur at transitions between sleep stages (Quan et al. 2011). A similar mechanism may account for the transient Notch-pathway oscillations observed during fate assignment in vertebrate neurogenesis (Momiji and Monk 2009).

In the case of primary generalized epileptic seizures, analysis of the clinical data has supported the hypothesis that the epileptic state coexists with the normal brain dynamics (Milton et al. 2017; Lopes da Silva et al. 1994; Milton 2000). From this point of view, the main difference between a person who does not experience seizures and one who does is the distance of the separatrix from the normal behavior in phase space. The smaller the distance, the more likely it is to spontaneously switch from one state to another. A biophysical computational model of this dynamics was proposed by Suffczynski et al. (2004). The model was validated using animal experimental and clinical data and a numerical bifurcation analysis. The model could specifically explain how the interaction between cortical neural populations and populations in the thalamus interact to produce the noise-induced transition to large-amplitude, slow frequency

rhythms. In addition, an analysis of simulations of external stimulation suggested that the termination of the epileptic state might be favorable at certain phases of the epileptic rhythm only whereas the desired result might be missed for stimulations at other phases.

In the case of focal and focal-onset seizures, an extensive study of the spatiotemporal dynamics of a model representing a piece of neocortical tissue pointed to a large number of potential dynamic mechanisms (Wang et al. 2014). It was proposed that detailed dynamic analysis of EEG or ECoG data might yield markers pointing to either the bifurcation or the bistability mechanism or a combination of both. For each subtype, specific treatment recommendations are indicated.

The concept of bistability also arises in studies concerning other neurological diseases, including migraine (see chapter ► “[Migraines and Cortical Spreading Depression](#)”) and bipolar affective disorders (see chapter ► “[Computational Psychiatry](#)”). Analysis of data of the spreading depression in migraine suggests a switch from the normal polarized state of the cortex to a totally depolarized state (Dahlem et al. 2008). This transition is supported by computational models of the cortical polarization state. However, the full dynamics of spreading depression is only given if the depolarization can propagate in space (see below). In the context of psychiatric disorders, high-level considerations have led to the proposal of a bistable mechanism for the occurrence of disorders of the bipolar spectrum. The interaction of a manic and a depressed state can lead to a bistable situation which exhibits both the possibility for regular transitions between the states (manic-depressive illness) and the possibility for perturbation-induced transition (e.g., the known phenomenon that antidepressants are able to induce the transition to the manic state (Goldbeter 2011)).

Excitability

Neurons are excitable and excitability can also be observed in large neural populations, e.g., in the human cortex. In an individual neuron, a well-defined depolarization threshold is found beyond

which an action potential can be induced. In neural populations within the living brain, it is difficult to do quantitative experiments but clinical observations point to similar mechanisms in some pathological cases. Notably, in patients with epilepsy, the so-called interictal spike is a candidate for suprathreshold response to stimuli from the surrounding brain tissue. Model studies support the idea that in some location on the cortex or within the hippocampus, the excitability threshold is lowered such that the surrounding activity occasionally reaches the excitation threshold and induces an abnormal response in the form of a single spike or sharp wave. In contrast to action potentials (which last on the order of a few milliseconds), the epileptic spike or sharp wave last on the order of 60–200 milliseconds. Cortical excitability has been proposed to be of clinical relevance to distinguish normal from abnormal tissue response. Valentin et al. (2005) studied the response of different cortical locations to single-pulse stimulations and concluded that simple excitability, a single population spike, indicated normal tissue. In the case of abnormally altered tissue, they frequently saw rhythmic responses that consisted of several oscillations before they disappeared. In addition, the epileptiform responses appeared to recruit wider cortical areas, i.e., they had a tendency to spread. A computational modeling study confirmed that spatially extended neural population models of human cortex gave single spike responses when the balance between excitation and inhibition was intact (Goodfellow et al. 2012a). In cases where locally diminished inhibition was assumed, the response to simulated perturbations was prolonged and rhythmic as in the clinical data. A modeling study of stimulation-induced afterdischarges showed that prolonged rhythmic transients are even possible in low-dimensional models when operating near the bifurcation to a bistable state (Baier et al. 2017). The predicted responses included rhythmic slow waves, spike waves, and poly-spike waves.

In an excitable neural medium like the neocortex, propagation of a disturbance can take the form of synchronized waves of neural activity.

Synchronization of neural population activity is involved in binding of sensory stimuli and organization of large numbers of neurons into synchronized waves lies at the basis of phenomena such as consciousness, cognition, and sleep and thought to underlie the generation of the EEG. Abnormal wave propagation arises in a number of neural conditions including flicker phosphenes (see chapter ► [“Flicker-Induced Phosphenes”](#)), drug-induced visual hallucinations (see chapter ► [“Visual Hallucinations and Migraine Auras”](#)), migraine (see chapter ► [“Migraines and Cortical Spreading Depression”](#)), stroke and the propagation of epileptic seizures (see (Milton and Jung 2003; Baier et al. 2012) and chapter ► [“Epilepsy: Computational Models”](#)). However, seizure propagation from an epileptic focus is exceedingly complex (Milton et al. 2009).

Moreover, it is difficult to obtain data on seizure propagation in humans since pathways involving subcortical and brainstem nuclei, for example, thalamo-cortical circuits, play major roles. The subject of seizure propagation represents an opportunity for computational neuroscience and may potentially point to treatment strategies designed to prevent or limit seizure propagation.

Spontaneous Bursting Behaviors

In dynamical systems, the subject of bursting behaviors falls under the broad subject heading of intermittency. There are several mechanisms that can generate intermittent (bursting) behaviors. In contrast to the bursting behaviors exhibited by single neurons (Izhikevich 2007), intermittency refers to patterns of burstiness in which both the size and timing of the bursts vary unpredictably. First, intermittency can be generated by purely deterministic mathematical models (Pomeau and Manneville 1980). This type of intermittency belongs to the class of chaotic systems and in low-dimensional systems is associated with inverse tangent, subharmonic, or secondary Hopf bifurcations. Despite the deterministic nature of the model, the timing (and size) of the laminar phases cannot be predicted. However, the probability distribution of the

duration of laminar phases is often associated with a power law (as is observed for the other mechanisms discussed below). Following some evidence from animal model data (Hramov et al. 2006), it has been shown that the occurrence of seizures in primary generalized epilepsy may be related to deterministic intermittency (Goodfellow et al. 2012b). Interestingly, the model resulted from the coupling of bistable local elements (cortical compartments) and introducing a certain degree of heterogeneity in the parameter for different cortical locations. The model predicts the spontaneous transition to the seizure and spontaneous termination and the essentially unpredictable nature of typical absence seizures.

A second mechanism that generates intermittency arises in slowly driven dissipative systems that self-organize themselves, without an external finetuning of control parameters, into a critical state near a state transitions. The critical state is characterized by a propensity to generate transient phenomena which occur on all length scales (Bak 1996; Sornette 2006). In this situation, abnormal discharges in the form of transient oscillations continue to appear and abort spontaneously even though the parameters are fixed and there are no external inputs. The transients are induced by internal (e.g., thermal) fluctuations. The key point is that the length of time between successive oscillatory bursts, or *laminar phases*, obeys a power law distribution. This means that laminar phases of all length scales are possible (Stead et al. 2010). Evidence for such power law behaviors has been obtained in the case of epileptic seizure recurrences (Osorio et al. 2011) and neuronal avalanches (see (Milton 2012; Beggs and Plenz 2003)). Although no general method is known that can prevent these recurrences, it is currently thought that some degree of predictability may be possible (Sornette and Ouillon 2012).

Finally, noise-induced type of intermittency referred to as *on-off intermittency* can arise in dynamical systems that are tuned close enough to a stability boundary (“edge of stability”) so that noisy perturbations causes transient switches

between two states (see chapter ► “[Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights](#)”). In the case that the noise enters through a parameter (multiplicative noise), power law behaviors arise (Cabrera and Milton 2002). This phenomena would be anticipated to arise generically in situations in which instability, such as manifested by epileptic cortex, is controlled by cortical and subcortical represented by delayed antagonistic dynamics (Cabrera 2005).

Computational Challenges

Dynamical behaviors can be combined with molecular and structural information to make a complete classification of neural disease. The modern day’s reductionist approach of associating with each disease a molecular defect is often not sufficient to base the development of therapeutic approaches. While temporal structure is obviously important for clinicians to diagnose and treat pathological states such as ventricular tachycardia, its role in diseases for which measurements with appropriate temporal resolution are not routinely available as, e.g., in pulsatile hormone release, is less obvious to the practicing physician. On the other hand, current dynamic disease approaches shed little light on the genesis of diseases such as epilepsy. In other words, what is the dynamic basis of epileptogenesis, namely, the process which describes why an initially seizure free individual, such as a child, develops over the course of many years, medically intractable epilepsy. Presumably the missing link is related to the self-organization of complex dynamical systems. The nonlinear dynamics of physiological processes assumes that macroscopic behavior is in the form of dissipative structures, namely structures which are maintained by a supply of energy. This implies that although the generating anatomical-physiological mechanisms may be rather complex, structural features can be studied properly in simplified models that omit certain details of the biological mechanisms. We stress that only in rather simple and abstract, nonlinear models, can current mathematical tools allow a thorough explanation of the basic mechanism of change between patterns that are associated with a transition to disease.

Questions of scale are central to dynamical approaches to disease. In other words, “How are dynamics at the length scale of molecules translated into behaviors that are observable at the bedside?” Our emphasis on simple models to investigate complex phenomena is based on the observation that complex dynamical systems can exhibit phenomena which are largely independent of scale. For example, limit cycle oscillations can be generated at the level of molecules, single neurons, small neural circuits, large neural populations, the human nervous systems, and human populations. Despite differences in the details and scales of the underlying mathematical models, limit cycles at all levels of organization share common properties with respect to the response to external perturbations including stability, similar responses to perturbations, and the capacity to synchronize with other oscillations.

Most nonlinear dynamical systems when tuned at the edge of stability exhibit low-dimensional dynamics (Guckenheimer and Holmes 1983). In particular, the center manifold theorem states that the dynamics at the edge of stability reduce to a low-dimensional normal form on a center manifold that can be written in terms of a first- or second-order differential equations referred to as the *normal forms*. Hence one would anticipate that one might be able to capture the dynamics for complex neural systems by using models based on the normal forms. An example occurs in the spring–thumb compression task in which a subject tries to compress a spring held between their thumb and index finger without causing the spring to buckle (Venkadesan et al. 2007). Mechanical considerations suggest that the likely normal form is the one that describes a pitchfork bifurcation, i.e.,

$$\frac{dx}{dt} = \mu x + x^3 - x^5, \quad (1)$$

where μ is a bifurcation parameter. This simple model is sufficient to capture the dynamics of this task observed in the laboratory.

A disadvantage of the normal form approach is that it does not necessarily capture the responsible

mechanism(s). Two approaches have been developed to try to close this gap. The first approach makes use of the phase resetting curve (PRC) for periodically spiking and bursting neurons (see chapter ► [“Phase Response Curves: Overview”](#)). The advantage is that the PRC can be measured experimentally. Models which incorporate the PRC have been quite successful in describing, for example, bistability in simple neural circuits (Foss and Milton 2000). Population models using the PRC approach exhibit many complex and counterintuitive dynamical properties (Timme and Wolf 2008).

The second approach uses neural mass models, such as that developed by Wilson and Cowan (see chapters ► [“Epilepsy: Computational Models”](#), ► [“Large-Scale Neural Networks: Vision”](#), ► [“Stochastic Neural Field Theory”](#), and ► [“Visual Hallucinations and Migraine Auras”](#)), to make a compromise between an abstract mathematical construct and a mechanistic biophysical model. In particular, it is possible to develop a statistical mechanics for neurodynamics (Buice and Cowan 2009) and then analytically derive the nature of the emergent properties that arise as a function of scale. However, the development of these statistical approaches requires that the effects of neuronal heterogeneity and connectivity pathways be suitably averaged. Thus it can become difficult to translate predicted dynamical behaviors into treatment strategies based on known molecular and neurophysiological mechanisms. Instead these models are more suited to capture the mean or population output of large numbers of neurons. They can also be used to investigate the nature of the underlying bifurcations and complex dynamical properties (Wang et al. 2012). By combining mathematical insight with mechanistic predictions, it is possible to explore, for example, the impact of inhibitory processes on a given pathophysiological phenomenon.

A further computational question concerns the role of time delays. Time delays are intrinsic components of the nervous system and arise because neural processing times and axonal conduction velocities are finite. The inclusion of time delays in computational models may become

increasingly important as the spatially extended nature of neural control mechanism is taken into account. There is a 10–20-fold difference in the conduction velocity between unmyelinated thin and larger diameter, myelinated axons of cortical neurons. Thus fast transfer of neural activity occurs initially in the direction perpendicular to the gray matter via corticothalamic, and intracortical and interhemispheric commissural fibers, whereas slow activity transmission occurs in parallel directions within the gray matter. These observations point to computational models of cortical dynamics which take the form of delay, or partial delay, differential equations (see chapter ► [“Time-Delayed Neural Networks: Stability and Oscillations”](#)) that include either multiple discrete delays or a distribution of delays.

The Future

The identification of the dynamical aspects of neurological disease motivates the development of dynamic treatment strategies. It is quite likely that proposed therapeutic strategies will be based on the use of external stimuli to control dynamics. The stimuli could be chemical, electrical, or mechanical (e.g., vibrations) and take the form of brief pulses or pulse trains. Even noisy signals can be of benefit (see chapter ► [“Stochastic Resonance: Balance Control and Cochlear Implants”](#)). Most present day implantable devices operate in an open loop mode, namely, the same stimulus or stimulus protocol is delivered regardless of the state of the patient’s nervous system. Examples include the vagal nerve stimulator for epilepsy, deep brain stimulators for Parkinson’s disease (see chapters ► [“Parkinson’s Disease: Deep Brain Stimulation”](#) and ► [“Computational Models of Deep Brain Stimulation \(DBS\)”](#)), and spinal cord stimulation for pain control and spasticity. An important observation is that all of these implementations do not benefit from insights potentially available from modeling efforts. Thus from the computational neuroscience point of view, the good news is that there is a lot of room for improvement.

Closed-loop treatment strategies have the advantage that the therapy is delivered based on

the state of the patient's nervous system (Milton and Jung 2003; Milton and Foss 1997). Such devices would likely take the form of implantable electronic computer devices which both monitor the important variables and then deliver the appropriate stimulus. Devices of this type have already been developed for treating epilepsy (Heck et al. 2014). An exciting development is the increasing availability of noninvasive, EEG sensors suitable for long-term uses (e.g., weeks, months) (Chi et al. 2012). Such data sets will likely prove invaluable since they will provide the first detailed insights into the nature of neurodynamics during a patient's daily life, as distinct from the behaviors observed in the physician's office and in the hospital bed. The availability of such information will impact the goals of computational neuroscience: (1) should more efforts be directed towards the prediction of rare events and (2) can computational neuroscience techniques be used to develop more efficient implementations of a control strategy, e.g., strategies that maximize battery life (changing a battery requires an operation). As an example, predictions of state-dependent responses to single-pulse perturbations were obtained from a model of primary generalized spike-wave seizure activity (Taylor et al. 2014). A closed-loop implementation was proposed which allowed to empirically test the success of stimulation in cases where real-time feedback is possible.

A further possibility for treating neurological disease is to simply replace the broken part with a new one. It may be eventually be possible to use stem cell techniques to produce the replacement part. However, it is more likely to be the case in diseases of the nervous system that the replacement part will take the form of an electronic circuit that can directly interface with the patient's nervous system. Existing examples include brain-motor prosthesis (see chapters ► "Functional Neuroscience: Cortical Control of Limb Prostheses" and ► "Cortical Motor Prosthesis"), exoskeletons, and insect robots. In some sense, computational neuroscience may be well suited for the design of such replacement neural circuits. After all the nervous system appears to be plastic

enough to adapt to whatever errors the circuits may have introduced. Thus we anticipate that computational approaches may play an important role in this area. And finally, there exist studies looking into the possibility of training patients to self-suppress epileptic seizures making use of brain-computer interfaces, e.g., by learning to control slow cortical potentials (Kotchoubey et al. 2001). However, regulation of slow cortical potentials in such settings is rather unspecific and the placebo effect may play a role. Recent applications of dynamic network analysis have led to the possibility to identify brain states with different susceptibility to more specific interventions, e.g., mental arithmetics (Muldoon et al. 2018). This raises the possibility that state-dependent cognitive activity might be employed to interfere with the evolution of an epileptiform brain activity.

Definition

Natural stimulations caused by objects in the surrounding world do not stimulate single sensory receptors in isolation but lead to the activation of large numbers of neurons simultaneously. Thus, typical stimulus variables of interest are represented only implicitly in activation patterns across large neural populations. These patterns are statistical in nature since repeated presentation of the same stimulus usually leads to highly variable responses. The large dimensionality and randomness of the neural responses make it difficult to assess how well different stimuli can be discriminated. Depending on how effectively neurons share the labor of encoding, the accuracy with which stimuli are represented can change

dramatically. Thus, studying the efficiency of population codes is important for our understanding of both which information is encoded in neural populations and how it is encoded.

Detailed Description

The question for the efficiency of population codes naturally arises if one seeks to relate the psychometric performance in a sensory discrimination task to the amount of information available from the activation of neural populations. For illustration, we consider an orientation discrimination task (Fig. 1a) for which the behavioral performance can be summarized by the *psychometric function* (Fig. 1b). The latter quantifies the discrimination error as a function of the stimulus parameter of interest. If one records from a neural population, one can use decoders to solve the same task on the basis of the neural responses and compare the resulting *neurometric performance* to the psychometric one. In addition, one can try to predict the behavioral choice from the neural responses which is quantified using the so-called choice probabilities.

Efficient Population Coding, Fig. 1 In each trial of an orientation discrimination task two gratings are presented as depicted in (a) where one of the two gratings is tilted to the right and the task is to say which of the two gratings is tilted. The task performance can be quantified by measuring the error frequency as a function of the tilt angle. The resulting *neurometric function* is sketched in (b)

For several tasks it has been observed that the neurometric function obtained for a single neuron or few is sufficient to explain the behavioral, psychometric performance. Given that the population of sensory neurons encoding for the stimulus contains many more neurons than just the recorded ones, this observation indicates that the *encoding* or the *decoding* of the task-relevant information from this sensory population is highly suboptimal: In case of *suboptimal encoding*, the information conveyed by each of these neurons is extremely redundant such that the entire population does not convey more information about the task than small subsets of neurons in this population (Zohary et al. 1994). In case of *suboptimal decoding*, the sensory population carries more information about the task than its individual neurons, but the readout of downstream neurons is unable to extract this distributed information (Beck et al. 2012).

The relationship between neural representation and behavioral performance can be studied using probabilistic modeling. In the beginning we will assume that the stimulus entity of interest is parameterized by a one-dimensional variable x (e.g., contrast, orientation, etc.). Later, we will also discuss the encoding of high-dimensional stimuli such as natural images in the context of normative approaches to population coding that investigate optimal encoding strategies from an engineering perspective.

Throughout this entry neural responses will be denoted by a vector $\mathbf{r}$ which oftentimes describes the spike counts of the different neurons but could similarly describe other properties such as response latencies, interspike intervals, or alike as well. Since the same stimulus usually leads to variable responses, the relationship between stimulus and population response is determined by the conditional probability distribution $p(\mathbf{r}|x)$. This conditional probability function specifies the encoding of the task-relevant stimulus variable.

Ideal Observer Analysis (Minimum Discrimination Error)

In order to assess how much information in principle can be extracted from a neuron or a population, it is necessary to determine the performance

Efficient Population Coding, Fig. 2 The decision boundary of the MAP estimator is located at the intersection of the two curves. Correspondingly, the minimum discrimination error is given by the shaded area

E

of an ideal observer. In a binary discrimination task with prior probabilities $p(x = x_1) = \lambda$ and $p(x = x_2) = 1 - \lambda$ for the two possible stimuli x_1, x_2 , the discrimination error is minimized by the maximum a posteriori (MAP) estimator $\hat{x}_{MAP} = x_1$ if $p(x_1 | \mathbf{r}) > p(x_2 | \mathbf{r})$ and $\hat{x}_{MAP} = x_2$ if $p(x_2 | \mathbf{r}) > p(x_1 | \mathbf{r})$. Correspondingly, the minimum discrimination error (MDE) is given by (see Fig. 2)

$$\text{MDE} = \int \min \{ \lambda p(\mathbf{r} | x_1), (1 - \lambda) p(\mathbf{r} | x_2) \} d\mathbf{r}$$

In case of Gaussian distributions $p(\mathbf{r} | x) = \mathcal{N}(\mathbf{r} | \mathbf{f}(x), C)$ with fixed noise covariance matrix C , one can show that the optimal classifier is linear and takes the following form:

$$\begin{aligned} \hat{x}_{MAP} = x_1 & \text{ if } \left(\vec{\mu}_1 - \vec{\mu}_2 \right)^T C^{-1} \left(\vec{x} - \langle \vec{\mu} \rangle \right) \\ & > \log \frac{\lambda}{1 - \lambda}, \quad \hat{x}_{MAP} = x_2 \quad \text{otherwise} \end{aligned}$$

$$\text{with } \mu_1 = \mathbf{f}(x_1), \mu_2$$

$$= \mathbf{f}(x_2), \text{ and } \langle \vec{\mu} \rangle = \frac{1}{2} \left(\vec{\mu}_1 + \vec{\mu}_2 \right)$$

Furthermore, if $\lambda = 1 - \lambda = 0.5$, the MDE is given by

$$\begin{aligned} \mathcal{F} \left(-\frac{d'}{2} \right) &= \int_{-\infty}^{-\frac{d'}{2}} \mathcal{N}(z | 0, 1) dz, \\ \text{where } d' &:= \sqrt{\left(\vec{\mu}_1 - \vec{\mu}_0 \right)^T C^{-1} \left(\vec{\mu}_1 - \vec{\mu}_0 \right)} \end{aligned}$$

In the absence of noise correlations, the noise covariance matrix C is diagonal. Its

dimensionality equals the number of neurons N and d' is of the order of $\sqrt{N}$. Thus, for uncorrelated noise the minimum discrimination error converges to zero in the limit of large N . In the presence of certain types of noise correlations, however, the error may saturate at a nonzero level. For example, this can happen in case of input noise which obviously cannot be removed by subsequent signal transmission (unless by the use of contextual side information).

As an illustration, consider the following linear encoding $\mathbf{r} = \mathbf{f}(x + n_x) + \mathbf{n}_r$ with $\mathbf{f}(x) = \mathbf{w}x$ where $n_x \sim \mathcal{N}(0, \sigma_x^2)$ denotes the input noise and $\mathbf{n}_r \sim \mathcal{N}(0, \sigma_r^2 I)$ constant additive output noise. In this case, the total noise covariance matrix reads $\mathbf{w} \sigma_x^2 \mathbf{W} + \sigma_r^2 I$, and its largest eigenvalue is given by $\sigma_x^2 + \sigma_r^2$ with eigenvector $\mathbf{w}$. The remaining $(n-1)$ dimensions belong to the same degenerated eigenvalue σ_r^2 . Using the Sherman-Morrison formula, it is possible to determine the inverse of this covariance matrix

$$C^{-1} = \frac{1}{\sigma_r^2} \left(I - \frac{\sigma_x^2 \mathbf{w} \mathbf{w}^T}{\sigma_r^2 + \sigma_x^2 \mathbf{w}^T \mathbf{w}} \right)$$

and

$$d' = \Delta x \cdot \sqrt{\frac{A}{1 + \sigma_x^2 A}} \quad \text{with } A := \frac{\mathbf{w}^T \mathbf{w}}{\sigma_r^2},$$

where A is of the order of N . Accordingly, for finite input noise $\sigma_x > 0$, the population sensitivity d' converges to $\Delta x / \sigma_x$ in the limit $N \rightarrow \infty$. This can be one reason why behavioral performance may be not much better than one would predict on the basis of the neurometric performance of very few neurons. By estimating

$(\Delta x/d')^2$ as a function of N for empirical data, one can use the following relationship

$$\left(\frac{\Delta x}{d'}\right)^2 = \sigma_x^2 + \frac{1}{A} \xrightarrow{N \rightarrow \infty} \sigma_x^2$$

for estimating the effective amount of input noise (see also Fig. 3).

Discrimination, Mutual Information, and Minimum Mean Square Estimation

The minimum discrimination error is only one way to evaluate the coding accuracy of a neural population. Other popular measures are based on the

mutual information between stimulus and response or minimum mean square estimation. In contrast to the discrimination approach, these other measures make assumptions about the stimulus distribution in order to obtain an average performance. If one assumes a binary stimulus distribution, the mutual information between stimulus and response is also called the Jensen-Shannon divergence which provides an upper and lower bound on the minimum discrimination error (see Fig. 4) but is not related to it in a one-to-one fashion (Berens et al. 2009). For Gaussian stimulus distributions, if we still assume a linear encoding and a Gaussian noise model, the joint distribution of stimulus and response is Gaussian, and mutual information as well as the minimum mean square error can be computed analytically. For nonlinear encodings and non-Gaussian noise models, these quantities are much more difficult to assess and approximation approaches are important.

Efficient Population

Coding, Fig. 3 The sensitivity index d' as a function of the number of neurons N in the presence (red) or absence (blue) of input noise

Efficient Population

Coding, Fig. 4 The minimum discrimination error can be bound from above and below (Berens et al. 2009) by the Jensen-Shannon information $H_B^1(1 - I_{JS}) \leq MDE \leq \frac{1}{2}(1 - I_{JS})$ where $H_B(u) = -u \log u - (1 - u) \log(1 - u)$ and the Jensen-Shannon information is equal to the mutual information $I_{JS} = I[x:r]$ between the stimulus x and the responses r

Fine Discrimination and Fisher Information

We cannot expect that neural encoding is accurately captured by a linear Gaussian model. Nevertheless, in the case of fine discrimination, when $|x_2 - x_1|$ is sufficiently small, d' can often be used to quantify approximately how well the two stimulus alternatives can be discriminated.

In a fine discrimination task, we study how well a stimulus at any location $x_1 = x$ can be discriminated from a stimulus with a slightly changed parameter value $x_2 = x + \Delta x$. Assuming that the tuning functions are smooth and the noise variance is finite, the discrimination performance approaches chance level $MDE \rightarrow 0.5$ in the limit of small differences in the stimulus parameter $\Delta x \rightarrow 0$. The asymptotic behavior in the limit of fine discrimination is more amenable to an analytical derivation of coding efficiency. Specifically, we can bound the minimum discrimination by the Jensen-Shannon information (see Fig. 2) which for small Δx can be approximated by the Fisher information:

$$I_{JS}(\Delta x) \approx \frac{f(x)}{8} \Delta x^2$$

Fisher information is defined as the variance of the score $V = \partial_x \log p(\mathbf{r} | x)$ conditioned on the stimulus x :

$$J(x) := \text{Var}[V | x] = E[V^2 | x]$$

where the second equality holds because it generally holds $E[V|x] = 0$. Many papers on neural coding refer to the Cramer-Rao bound to motivate the evaluation of Fisher information which gives a lower bound on the mean squared error of any unbiased estimator:

$$E[(\hat{x}_{\text{unbiased}}(\mathbf{r}) - x)^2 | x] \geq \frac{1}{J(x)}$$

This bound, however, is only of intuitive use for the evaluation of encodings as it does not account for the fact that the signal x must be a random variable and the precision with which

x can be decoded strongly depends on the stimulus distribution $p(x)$. Similarly, the local expansion of the Jensen-Shannon divergence must be wrong whenever I_{JS} exceeds 1 bit since it generally holds $I_{JS} \leq 1$ bit. Thus the approximation for fine discrimination only holds if

$$\Delta x^2 \ll \Delta x_c^2 \equiv \frac{8}{J(x)}$$

In the next section, we will discuss the evaluation of population codes if the stimulus distribution $p(x)$ is given.

Coding Efficiency and Optimal Encodings

The question of coding efficiency critically depends on the stimulus distribution $p(x)$ which often requires additional considerations that go beyond the framework of discrimination. While for each pair of stimuli tested for in a discrimination task the prior distribution is reduced to two discrete alternatives, for continuous stimulus parameters in principle, any pair of stimuli could be picked. Therefore, one often rather wants to assess the coding efficiency for a prior distribution that describes how the stimulus parameter is distributed under natural conditions. For example, if the stimulus parameter is contrast or speed, one would assume that the natural distribution has a unimodal density over the positive real axis which takes its maximum at zero and is monotonically decreasing.

To be able to compare the performance of two coding schemes, it is necessary to use a measure that provides a unique ordering relation. A direct ranking of neurometric functions, for example, is not possible unless in the special case if one function lies uniformly above or below the other one. If one was interested exclusively in fine discrimination, one could compare just the slope of the neurometric function at chance level describing how fast the MDE drops from chance level and ignore the discrimination performance for larger differences in the stimulus parameter. In most cases however, one would rather be interested in

the average performance when the stimuli are drawn from the natural distribution. The corresponding notions and assessments of coding efficiency can be very different. The optimization for fine discrimination is tightly related to optimizing Fisher information, whereas an optimization of the average discrimination error (Berens et al. 2011) is more similar (but not equivalent) to optimizing mutual information (Yarrow et al. 2012) or the minimum mean squared error.

There is a special condition for which the minimum mean squared error is determined by Fisher information. If the responses of the different neurons can be described as independent, identically distributed (i.i.d.) observations or more generally if the conditions of the central limit theorem are fulfilled, then Fisher information can be used to determine an asymptotic approximation of the decoding error (Bethge et al. 2002). Optimal codes, however, generically exhibit highly heterogeneous encodings which preclude the use of the central limit theorem. In particular, one should note that the linear increase of Fisher information in case of i.i.d. observations corresponds to a very slow logarithmic growth in mutual information. In contrast, encodings that are optimized for mutual information usually achieve a much faster, linear growth of the mutual information. The two situations can be illustrated with the following two prototypical examples:

$$\begin{aligned} \text{iidcoding} : p_{iid}(\mathbf{r}, \mathbf{x}) &= p(\mathbf{x}) \prod_{k=1}^N p(r_k | f(\mathbf{x})) \quad \text{vs} \\ \text{factorial} \\ \text{mathrmcoding} : p_{fac}(\mathbf{r}, \mathbf{x}) &= p(\mathbf{x}) \prod_{k=1}^N p(r_k, f_k(\mathbf{x})) \end{aligned}$$

It is easy to derive (Brunel and Nadal 1998) that for the left example of i.i.d. coding mutual information grows only logarithmically, $I[\mathbf{r}, \mathbf{x}] \propto \log(N)$, whereas for the right example of a factorial code (Nadal and Parga 1994), mutual information grows linearly, $I[\mathbf{r}, \mathbf{x}] \propto N$. Thus, for large populations of neurons, i.i.d. coding is highly inefficient compared to factorial coding.

In cases other than i.i.d. coding (or, more generally, whenever the conditions for the central limit theorem are not fulfilled), the behavior of Fisher information can be very different from that of mutual information. For example, it is possible to build factorial codes for which Fisher information grows only linearly in N just like in the case of i.i.d. coding, but an exponential or super-exponential growth of Fisher information is possible as well. Conversely, it is easy to construct encodings for which Fisher information grows arbitrarily fast with N , but this does not imply that mutual information grows linearly (Bethge et al. 2002). Fisher-optimal codes are exclusively optimized for fine discrimination and may exhibit extremely poor performance for any discrimination for which $\Delta x^2 \geq \Delta x_c^2$.

Task Dependence of Coding Efficiency

While it is obvious that coding efficiency is highly task dependent, it is important to understand the implications of this task-dependency for the interpretation of the available experimental data. As mentioned in the beginning of this entry, it is typically observed that the neurometric function obtained for a single neuron or few is sufficient to explain the behavioral, psychometric performance and that this may hint to highly inefficient encoding or decoding. If the encoding is fixed (i.e., independent of the task), it is straightforward to show that the efficiency of the encoding will depend on the task. For illustration, let us assume we have the same number of neurons as stimulus dimensions and the following encoding with independent noise model:

$$p_{enc}(\mathbf{r} | \mathbf{x}) = \prod_{k=1}^N p(r_k | x_k)$$

Depending on which stimulus distribution $p(\mathbf{x})$ we use, one can obtain either a highly redundant i.i.d. coding scheme or a maximally efficient factorial code. Specifically, if we set $p(\mathbf{x}) = \prod_{k=1}^N p(x_k)$ we obtain the maximally efficient factorial code

$$p_{enc}(\mathbf{r} | \mathbf{x})p(\mathbf{x}) = \prod_{k=1}^N p_{enc}(r_k | x_k)p(x_k) \\ = \prod_{k=1}^N p(r_k, x_k),$$

whereas if we choose a stimulus distribution $p(\mathbf{x}) = p(x_1)\prod_{k=2}^N \delta(x_k - x_1)$, for which it always holds $x_1 = x_2 = \dots = x_N$, we then obtain the highly redundant i.i.d. coding scheme. The first example roughly corresponds to a task where any two images are to be discriminated, while in the second case only full-field uniform gray images need to be discriminated.

The mutual information between stimulus $\mathbf{x}$ and population response $\mathbf{r}$ cannot be larger than the entropy of the stimulus distribution. For good reasons, typical laboratory tasks are inherently biased toward low entropy stimuli. More specifically, most experiments are designed such that it is not critical which neurons exactly are recorded. In vision, this is achieved by using global homogeneous stimuli such as global motion patterns or gratings. By varying only one parameter of these stimuli like the net velocity or orientation, it is achieved that all neurons encode the same parameter in an i.i.d. fashion. Correspondingly, mutual information cannot grow faster than logarithmically with the number of neurons yielding a highly suboptimal population coding strategy.

For many tasks, however, it is likely that this type of suboptimality is not sufficient to explain why behavioral performance does not utilize more information than provided by a single or few neurons. For spatially homogeneous stimuli, the information of neurons with different receptive field locations should still accumulate such that doubling the number of neurons should reduce the squared error by a factor of two as predicted by an i.i.d. coding scheme. This fact, however, is not consistent with the observation that the information of a local population of neurons reaches behavioral performance. Thus, it seems that for typical low-level tasks, the readout cannot integrate information from different local regions.

In conclusion, both encoding and decoding are likely to render behavioral performance highly suboptimal in case of common laboratory tasks for which the decision space has low entropy and for which the stimulus size is rather large. In the future, important new insights about principles of neural coding and sensory decision making may be obtained by choosing more ecologically relevant tasks such as natural scene classification. The importance of studying natural tasks may be corroborated by the example of grid cell encoding in hippocampus. Despite the fact that the stimulus parameter is only two dimensional – namely, the x-y position of the animal – the mutual information between this stimulus parameter and the grid cells scales proportional to the number of neurons (Sreenivasan and Fiete 2011; Mathis et al. 2012). Similarly, one would expect a linear growth of mutual information for the encoding of natural images in the visual system.

Definition

Spike-timing-dependent plasticity refers to correlated activity of neurons that leads to long-term strengthening or weakening of connections, depending on the order of firing of pre- and postsynaptic neurons. The relative timing of pre- and postsynaptic spiking determines the extent and direction of synaptic changes but should not exceed 50 ms. Repetitive postsynaptic spiking, within this time window, after presynaptic activation results in strengthening of connections. Conversely, presynaptic spiking that follows postsynaptic activation produces long-term weakening of connections. Hebbian electrical-conditioning paradigms seek to modulate synaptic connectivity by promoting synchronous neuronal activity based on these rules and

have important implications for augmenting spared pathways that may be weakened by injury or disease.

Detailed Description

Spike-Timing-Dependent Plasticity

In 1949, Donald Hebb stated “When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A’s efficiency, as one of the cells firing B, is increased.” This is known as Hebb’s postulate of learning (Hebb 1949). Manipulations of neuronal activity based on this mechanism have been used extensively to modify the strength of connections.

Seminal studies in the late 1990s built on Hebb’s postulate (Hebb 1949) to define the temporal relationship between spiking in pre- and postsynaptic neurons, which dictates the polarity of plastic changes (i.e., potentiation vs. depression). In different neuronal preparations, ranging from neocortical slices (Markram et al. 1997), hippocampal slices (Debanne et al. 1998), and hippocampal cell cultures (Bi and Poo 1998), long-term strengthening of connections was observed if presynaptic action potentials consistently preceded postsynaptic firing by no more than 50 ms. Conversely, presynaptic action potentials that followed postsynaptic spikes produced long-term weakening of connections. Furthermore, the largest changes in synaptic efficacy occurred when the latency between the firing of the pre- and postsynaptic cells was small, and there was a sharp reversal from strengthening to weakening as this latency passed through zero. This form of synaptic modification has been referred to as spike-timing-dependent plasticity (STDP).

STDP-Based Approaches for Strengthening Neural Pathways and Promoting Recovery After Injury

STDP rules (Bi and Poo 1998) have been employed *in vivo* in rats and monkeys to regulate the timing of activity across synapses in an effort to induce Hebbian plasticity. Jackson et al.

employed an autonomous head-fixed recurrent brain-computer interface, called the neurochip (Jackson et al. 2006a; Mavoori et al. 2005), in the primary motor cortex of behaving macaque monkeys to strengthen cortico-cortical connections (Jackson et al. 2006b). Action potentials recorded from a presynaptic neuron were used to trigger delivery of single stimulus pulses to neighboring cortical cells. The stimulation was timed to activate postsynaptic neurons, to which the triggering cell projected, with a specific delay. Electrical conditioning was delivered for 2 days using the neurochip while animals engaged in free behavior in their home cages. After conditioning with a 5-ms spike-stimulus delay, the movement representation of the presynaptic recording site shifted toward that of the postsynaptic stimulated site, presumably due to strengthening of the connection from the pre- to the postsynaptic site, while the output from nearby (unstimulated) control sites remained unchanged (Fig. 1). The extent of the change was dependent on the spike-stimulus delay, consistent with the STDP rule (Bi and Poo 1998). Importantly, the induced Hebbian plasticity persisted for more than a week in some cases.

In a second example, Nishimura and coworkers modified the strength of connections between the motor cortex and the spinal cord with the neurochip (Jackson et al. 2006a; Mavoori et al. 2005) in monkeys (Nishimura et al. 2013). Electrical stimuli, triggered by action potentials of single corticomotoneuronal cells, were delivered in the spinal cord during free behavior. The activity-dependent stimulation modified the strength of corticomotoneuronal connections to motoneurons, which was documented with spike-triggered averages of electromyographic activity (EMG) in target muscles. In this study, both strengthening and weakening of connections was observed, using different spike-stimulus delays. In some cases, the effects lasted for days after the end of conditioning. Notably, delays of 50 ms and longer didn’t produce significant changes despite involving the same amount and pattern of spinal stimulation, thus emphasizing the importance of the relative timing of stimulation on the induced plasticity.

Electrical Conditioning for Spike-Timing-Dependent Plasticity of Neural Circuits, Fig. 1 Reorganization of motor output using a closed-loop electronic neural interface. **(a)** Intracortical microstimulation (ICMS) at three neuronal sites in the motor cortex, designated as Nrec, Nstim, and Nctrl, with the monkey at rest, evoked distinct muscle responses (Mrec, Mstim, and Mctrl, respectively), which were measured using EMG and two-dimensional isometric wrist torques (left and middle panels). Right panel shows the average wrist-torque responses to ICMS, superimposed on the flexion-extension (F-E) and radial-ulnar (R-U) axes. **(b)** Cortical conditioning with the neurochip (Jackson et al. 2006a; Mavoori et al. 2005)

involved 2 days of triggered microstimuli at Nstim for every spike recorded at Nrec during free behavior and sleep. **(c)** Post-conditioning ICMS of Nrec activated Mstim, presumably through strengthening of horizontal projections to Nstim, and Mrec through the direct projection, while the outputs from Nctrl and Nstim remained unchanged. The mean torque generated by ICMS at Nrec also shifted toward the output produced by Nstim. For **(a)** and **(c)**, arrows in the right panels indicate means of 200-ms torque trajectories, denoted by the dashed lines. (Image adapted, with permission, from Jackson et al. 2006b)

Proxies for neuronal activity have also been used to induce Hebbian-like plasticity. In monkeys, Lucas and Fetzi used EMG signals from contralateral forelimb muscles to trigger stimulation of sites in the primary motor cortex associated with different (forelimb) muscles (Lucas and Fetzi 2013). The neurochip (Jackson et al. 2006a;

Mavoori et al. 2005), in this case, was used to transform forelimb EMG into subthreshold intracortical stimuli, which were delivered during hours of unrestrained behavior. As observed by Jackson et al. (2006b), EMG-triggered conditioning promoted a shift in the movement representation of the presynaptic recording site toward that

of the postsynaptic stimulated site, presumably due to strengthening of the connection from the pre- to the postsynaptic site. Importantly, the output from nearby control sites that received pseudoconditioning remained unchanged. Reorganization was observed within 25 min and could be maintained with intermittent conditioning for up to 5 days. Moreover, reorganization was site specific (occurring only at the presynaptic site) and input specific (occurring only with EMG-triggered stimulation). Control stimulation that was independent of muscle activity failed to produce reorganization, yet again underscoring the importance of timing over open-loop stimulation approaches. Lastly, this investigation provided evidence for muscle activity being an effective surrogate of associated cortical activity for producing targeted reorganization of the motor cortex, implying that the timing of activity in the motor output of cortical sites is sufficiently correlated to its neuronal activity for mediating conditioning.

The studies highlighted above provided important insights into the capability of activity-dependent electrical stimulation for remodeling neural connections during behavior. Corresponding to these fundamental research opportunities are prospects for translating circuit-retraining investigations into clinical therapies. By delivering stimuli synchronized with cell activity, continuous operation of recurrent brain-computer interfaces can strengthen neural connections weakened by disease or trauma. This paradigm was explored by McPherson et al. to promote forelimb-motor recovery after chronic cervical spinal cord injury (SCI) in rats (McPherson et al. 2015). Delivery of intraspinal microstimulation below the injury was synchronized with arrival of functionally related volitional motor commands, signaled by EMG in the impaired forelimb, a paradigm similar to that developed by Lucas and Fetz (2013). Stimulation was delivered for 5–8 h/weekday for 3 months during which the rats also received physical retraining on a reach-and-grasp behavior that encouraged use of the impaired forelimb. Rats that received the targeted activity-dependent spinal stimulation (TADSS) exhibited markedly

enhanced recovery compared to the two control groups that received targeted open-loop spinal stimulation (TOLSS) or physical retraining alone. Moreover, the therapeutic benefits of TADSS persisted for at least 3 weeks after the stimulation had ended (Fig. 2).

The maintenance of TADSS-driven recovery for 3 weeks beyond the intervention is both a novel and clinically significant finding (McPherson et al. 2015). It distinguishes TADSS from most open-loop electrical-stimulation therapies, whose benefits are often contingent on the continued delivery of stimulation. Additionally, this finding strongly suggests that the enhanced and lasting recovery afforded by TADSS is an effect unique to activity-dependent conditioning of specific neural circuits. Consistent with this notion, spike-triggered intracortical stimulation delivered for 3 weeks restored communication between motor and somatosensory areas in the cerebral cortex after focal traumatic-brain injury in adult rats, leading to accelerated forelimb-motor recovery compared to open-loop intracortical stimulation (Guggenmos et al. 2013). Cortico-pallidal stimulation, contingent on the occurrence of action potentials in the globus pallidus or the primary motor cortex, was also more successful in ameliorating parkinsonian akinesia and pathological neuronal discharges in monkeys compared to continuous high-frequency deep-brain stimulation (Rosin et al. 2011; Santos et al. 2011). Lastly, transcranial electrical stimulation triggered by local-field-potential activity during a spike-and-wave episode, a common signature of an epileptic seizure, reduced seizure duration by 60% on average in a rat model of generalized epilepsy (Berényi et al. 2012).

Paired-associative stimulation has also been used for inducing Hebbian plasticity. Taylor and Martin altered the strength of corticomotoneuronal synapses by repeatedly pairing transcranial-magnetic and peripheral-nerve stimuli at different interstimulus intervals to produce bidirectional plasticity in human subjects (Taylor and Martin 2009). The induced plasticity influenced the voluntary motor output, producing a bidirectional modulation in both the EMG and force output. Thus, a protocol designed

Electrical Conditioning for Spike-Timing-Dependent Plasticity of Neural Circuits, Fig. 2 EMG-triggered intraspinal stimulation promotes motor recovery after chronic SCI. Rats were trained on a forelimb reach-and-grasp pellet-retrieval task before injury. Starting 6 weeks post injury, animals received 13 weeks of one of three different types of treatments. Over 13 weeks of treatment, animals receiving physical retraining and TADSS (red) recovered to a significantly greater extent than animals that received either physical retraining and TOLSS (blue) or physical retraining alone (black). After 13 weeks of intervention, the TADSS animals had recovered to 63%

of their pre-SCI skilled-reaching performance, whereas the TOLSS and physical-retraining-only cohorts averaged 30% and 31%, respectively. Importantly, the therapeutic benefits of TADSS persisted for at least 3 weeks after the stimulation had ended. Note that the performance of TOLSS and physical-retraining-only cohorts was statistically indistinguishable from each other. Y-axis shows the average weekly reaching scores across all rats in each cohort expressed as a percentage of each rat's pre-SCI maximum. Error bars represent standard error of the mean. (Data replotted from McPherson et al. 2015)

to induce synaptic STDP produced concurrent changes in corticospinal transmission and altered normal physiological motor output. This strategy was used by Bunday and Perez to strengthen pathways weakened by injury in humans with chronic incomplete cervical SCI (Bunday and Perez 2012). Using noninvasive techniques, they precisely timed the arrival of descending and peripheral volleys at corticomotoneuronal synapses of an intrinsic finger muscle. Corticospinal neurons were activated via transcranial magnetic stimulation delivered over the hand representation of the motor cortex, and spinal motoneurons were activated antidromically through peripheral-nerve stimulation delivered to the wrist. Consistent with STDP-learning rules (Bi and Poo 1998), they found that arrival of presynaptic volleys prior to motoneuron discharge enhanced corticospinal

transmission and voluntary motor output. The reverse order of volley arrival decreased voluntary motor output and electrophysiological outcomes. The induced plastic changes lasted for up to 80 min after 17 min of paired stimulation. Cortical and peripheral-nerve stimulation have also been paired by Perez and coworkers to change transmission at spinal synapses of lower-limb motoneurons in humans with chronic incomplete SCI (Urbin et al. 2017). Thus, STDP of residual corticomotoneuronal synapses holds considerable promise for improving motor function after SCI.

Finally, a recent study by Bunday et al. found that volitional activity during a paired corticomotoneuronal stimulation protocol enhanced corticospinal transmission in humans with SCI (Bunday et al. 2018). Transmission was significantly improved when the paired

stimulation was combined with relevant muscle activity compared to delivery of stimulation at rest, underscoring the role of volitional activity, which occurs at a very different timescale from STDP (Drew and Abbott 2006), in boosting synaptic plasticity. A similar observation was made almost three decades ago by Ahissar et al., who found that strengthening of cortical connections was strongly dependent on the behavioral context of the stimuli that induced such modifications (Ahissar et al. 1992). Correlated activity of neurons was often necessary, but not sufficient, for induction of plasticity.

STDP: Complexities and Challenges

In some studies, STDP-based stimulation protocols produced global modifications of synaptic strength, affecting connections beyond the site of induction. Poo and coworkers found presynaptic propagation of long-term potentiation (LTP) from the site of induction (Hui-zhong et al. 2000). LTP propagated retrogradely to glutamatergic synapses on the dendrites of the presynaptic neuron and laterally to those made by its axonal collaterals onto other glutamatergic cells. No postsynaptic lateral or forward propagation or secondary propagation of LTP to synapses not directly associated with the presynaptic neuron were observed. Such selective propagation would require the existence of long-range cytoplasmic signaling within the presynaptic neuron, triggered, in turn, by a retrograde messenger. The researchers also found that the spread of long-term depression (LTD) followed a similar pattern of presynaptic propagation (Fitzsimonds et al. 1997). Brain-derived neurotrophic factor (BDNF) and nitric oxide, secreted as a result of LTP and LTD induction, were implicated in triggering retrograde potentiation and depression, respectively (Du et al. 2009).

Other studies have also reported the spread of LTP to nearby connections from the activated synapse but have not found such a selective pattern of propagation (Bonhoeffer et al. 1989; Engert and Bonhoeffer 1997; Schuman and Madison 1994). Engert and Bonhoeffer, for example, found that there was no input specificity at a distance less than 70 μm from the activated synapse (Engert and Bonhoeffer 1997). Synapses in

close proximity to the site of LTP induction were potentiated, regardless of their own history of activation, whereas synapses far away showed no potentiation, a stark contrast to the LTP-propagation pattern observed by Poo and coworkers (Hui-zhong et al. 2000). Nevertheless, these studies all highlight the lack of target specificity associated with STDP protocols.

The patterns of activity that induce changes in strength of synapses that involve inhibitory neurons are quite diverse and differ markedly from synapses that involve excitatory cells alone. Involvement of γ -aminobutyric acid-ergic (GABAergic) neurons leads to a variety of STDP-timing dependencies (Bi and Poo 1998; Holmgren and Zilberter 2001; Woodin et al. 2003). Woodin et al., for example, showed that repetitive postsynaptic spiking within 20 ms both before and after the activation of GABAergic synapses led to persistent increases in synaptic strength in rat hippocampal cultures and slices (Woodin et al. 2003). Changes in synaptic strength could also be induced by postsynaptic activity alone (Kurotani et al. 2008; Sieber et al. 2013). Furthermore, LTP- and LTD-propagation patterns in networks containing GABAergic neurons deviated from those observed within excitatory pathways (Fitzsimonds et al. 1997; Hui-zhong et al. 2000).

Implementation of STDP-based approaches in vivo poses other complexities. Several studies have noted a variability in both the extent and duration of plasticity across conditioned sites (Jackson et al. 2006b; Lucas and Fetz 2013; Nishimura et al. 2013), making it difficult to predict the effects of conditioning for a given site pair. In a recent study by Seeman et al., paired stimulation delivered to the sensorimotor cortex of awake behaving monkeys, at fixed intervals consistent with the STDP window (Bi and Poo 1998), failed to induce changes at 13/15 tested site pairs (Seeman et al. 2017). Moreover, the stimulation protocol often produced increases in global excitability or depression of the conditioned pair. Secondly, the use of proxies, such as EMG (Lucas and Fetz 2013; McPherson et al. 2015) or movement, for inducing STDP undoubtedly produces a range of firing latencies between pre- and

postsynaptic neurons in the conditioned pathways. The most parsimonious explanation for how such protocols lead to STDP, despite only loosely controlling spike timing, is that activity-dependent stimulation generates a statistical preponderance of spike pairs with the appropriate intervals. Nonetheless, additional work is needed to reconcile the large discrepancy in timescales: protocols relying on proxies of neuron spiking involve temporal associations on the order of one or more seconds, while STDP occurs over timescales of tens of milliseconds (Drew and Abbott 2006). Thirdly, the mechanisms by which behavior enhances the effects of conditioning, as seen in experiments by Ahissar et al. (1992) and Bunday et al. (2018), are also unclear. In unpublished work by Moorjani et al., movement-triggered stimulation produced significant and lasting strengthening of cortico-cortical connections in monkeys only when paired with relevant muscle activity. Neither movement alone nor stimulation alone produced similar effects, yet again emphasizing the importance of behavioral context on the resultant plasticity.

Complexities and challenges abound, but it has been demonstrated unequivocally that STDP-based electrical-stimulation protocols can modulate synaptic connections during normal behavior. These approaches drive endogenous-plasticity mechanisms rather than producing a generalized increase in excitability alone. Consequently, they offer promise for functional and lasting reorganization of neural circuitry impaired by injury. Combination with other strategies, such as targeted delivery of plasticity-enhancing neuromodulators, may further enhance and prolong the duration of effects achieved using activity-dependent or paired-associative stimulation (Moorjani 2016; Silver and Miller 2004). For example, a large body of work has shown that BDNF (Cotman and Berchtold 2002; Kohara et al. 2001), much like a neurotransmitter and unlike a neurotrophin, and its high-affinity receptor, tropomyosin-related kinase B (TrkB; Meyer-Franke et al. 1998), are transported retrogradely and anterogradely to synapses in an activity-dependent manner. Once at the synapses, BDNF binds to presynaptic TrkB receptors to modify

neurotransmitter release (Cotman and Berchtold 2002). Postsynaptically, BDNF modifies sensitivity (Cotman and Berchtold 2002), e.g., through its interactions with N-methyl-D-aspartate receptors (which are necessary for induction of LTP; Bi and Poo 1998). This activity-dependent signaling ultimately results in changes in neuronal morphology (Horch and Katz 2002; Ji et al. 2010) and potentiation of synaptic transmission (Cotman and Berchtold 2002; Ji et al. 2010; Kovalchuk et al. 2002). These studies suggest that targeted delivery of BDNF can potentially strengthen and prolong the duration of plasticity achieved using STDP-based stimulation approaches and exploration of such combinatorial interventions may represent important future directions.

Definition

ECoG refers to the invasive technique of recording brain electrical field potentials with electrodes placed directly on the cortical surface. ECoG electrodes are typically placed subdurally, above the

pia mater. In humans, ECoG is often conducted in patients with medically intractable epilepsy in order to monitor their seizures. Because a craniotomy (a surgical incision into the skull) is required to implant the electrode grid, ECoG is an invasive procedure. Clinical ECoG offers a rare and invaluable research opportunity for obtaining invasive electrophysiological signals in awake, behaving humans. Another avenue of research that is beginning to be explored is cortical stimulation using ECoG electrodes (e.g., Parvizi et al. (2013)). The electrode grids often cover much wider areas than the epileptogenic zone, allowing recordings from healthy brain tissue. A postoperative CT scan allows visualization of the electrodes and documentation of their positions in relation to skull geometry (Fig. 1a). By co-registering the CT scan with a preoperative MRI scan, the precise locations of the electrodes on the cortical surface can be determined (Fig. 1b). Such co-registration allows the comparison between ECoG signals and

Electrocorticogram (ECoG), Fig. 1 Spatial topography of electrode coverage in an example patient. Electrocorticogram (ECoG), Fig. 2 Sample human ECoG recordings and power spectra. (a) Raw activity traces from three ECoG electrodes in a neurosurgical patient. Electrodes #1 and #2 were over the left frontal cortex, electrode #3 over left temporal cortex. Data were recorded using DC-coupled amplifier with a 500-Hz sampling rate. Two 10-s-long segments are shown. Arrows

point to examples of oscillations. (b) Power spectra for the three electrodes shown in a, averaged over 83-min recording during the awake state. The spectra are presented in log-log scale, under which a power-law distribution manifests as a roughly straight line ($\log(P) \propto -\beta \log(f)$). (Adapted from He et al. (2010))

functional magnetic resonance imaging (fMRI) data obtained in the same subject. As with other types of brain field potentials, such as local field potentials (LFPs), ECoG signals are a mixture of arrhythmic activity and brain oscillations (Fig. 2a). In this entry, we will specifically address computational modeling of arrhythmic ECoG activity.

Detailed Description

Brain Oscillations Versus Arrhythmic Brain Activity

Brain oscillations are recurring patterns of brain activity that follow a particular temporal beat. For example, the first discovered EEG rhythm, the occipital alpha wave, proceeds at roughly 10 cycles per second (Berger 1929). Thus, brain oscillations (arrows in Fig. 2a) are most easily identified in the frequency domain, as their power spectra contain a peak at the corresponding frequency (Fig. 2b). There are a number of brain oscillations at different frequencies, each with their own underlying mechanisms and cognitive functions (Buzsaki et al. 2013).

At the same time, the power spectrum of brain field potentials contains a predominant “ $1/f$ ” component; that is, power tends to fall off with increasing frequency following a power-law function: $P \propto 1/f^\beta$, where P is power, f is frequency, and β is a parameter (typically in the region of 0–3) named the “power-law exponent” (Fig. 2b). A power-law function is indicative of scale invariance, suggesting that no particular time scale or frequency dominates the dynamics. Hence, the brain activity contributing to this $1/f$ slope in the power spectrum is devoid of periodicity (i.e., being arrhythmic or “scale-free”). Note that white noise (including Poisson firing patterns) is a special case of arrhythmic activity, in which case β equals 0. A power-law distribution of the power spectrum is characteristic of the temporal dynamics of brain activity at many different observational levels: It has been described in the fluctuations of neuronal membrane potentials, LFP, ECoG, EEG and magnetoencephalography (MEG) recordings, and fMRI signals. In addition, the amplitude fluctuations of narrowband brain oscillations in EEG/MEG recordings exhibit prevalent scale-free dynamics (Linkenkaer-Hansen et al. 2001). A power-law distribution has also been reported in the statistics of neurotransmitter

release (Lowen et al. 1997) and neuronal firing (Lowen et al. 2001), where it has been more controversial. Lastly, fluctuations of human behavioral output such as reaction times, hit rate, and force have often been found to exhibit a $1/f$ -like power spectrum as well (Gilden 2001; Kello et al. 2010).

Modeling the Arrhythmic ECoG Signals

Studies investigating the power spectrum of ECoG and LFP signals have reported very similar values for the power-law exponent, which is typically in the range of 2–3 (Freeman and Zhai 2009; He et al. 2010; Miller et al. 2009; Milstein et al. 2009). Similar power-law exponents were found in the power spectrum of neuronal membrane potential fluctuations (Destexhe et al. 2003; El Boustani et al. 2009). In particular, two studies using human ECoG, focusing on the relatively low-frequency (from <0.01 to 100 Hz) (He et al. 2010) and relatively high-frequency (10–500 Hz) (Miller et al. 2009) ranges, respectively, have reported strikingly similar exponents in the middle-frequency range: $\beta = 2.44$ in the range of 1–100 Hz in the first study, and $\beta = 2.46$ in the range of 15–80 Hz in the second study. The close alignment of these numbers exemplifies the robustness of the scale-free distribution.

In addition to this middle-frequency range, Miller et al. (2009) found a transition to $\beta \approx 4$ in the high-frequency range above 75 Hz. They proposed a simple model that can explain the power spectral shape, which utilizes the convolution of two exponentially decaying functions representing, respectively, the postsynaptic current and the membrane leak. An exponentially decaying function in the time domain is characterized by a “Lorentzian” function in the frequency domain of the form $P \approx \text{constant}$ for $f < \ll f_0$ and $P \propto 1/f^2$ for $f \gg f_0$, where f_0 is the “knee” frequency. The “knee” frequency is directly related to the time constant τ of the exponential decay such that $f_0 = 1/(2\pi\tau)$. Recalling that convolution in the time domain is equivalent to multiplication in the frequency domain, the

resulted power spectrum from this model is thus the multiplication of two Lorentzians, following the form $P \approx \text{constant}$ for $f < \ll f_1$, $P \propto 1/f^2$ for $f_1 < \ll f < \ll f_2$, and $P \propto 1/f^4$ for $f \gg f_2$, where f_1 and f_2 are two “knee” frequencies determined by the time constants.

The locations of f_1 and f_2 can be determined empirically. While Miller et al. found f_2 to be around 75 Hz, their data do not reveal the location of f_1 in the lower-frequency range. This information is provided in He et al. (2010), which found f_1 to be around 1–2 Hz. Together, these results suggest the existence of two time constants: one around 2–3 ms and another around 100 ms. At present, the origins of these time constants remain a speculation. One possibility is that the 2–3 ms time constant originates from synaptic current and the ~ 100 ms time constant from membrane leak (Miller et al. 2009). An alternative possibility is that the ~ 100 ms time constant comes from the slow NMDA synaptic current (Gibb and Colquhoun 1991; Wong and Wang 2006) and the membrane time constant can be as short as 2–3 ms during active synaptic activity (Koch et al. 1996). Adjudication between these two scenarios will require future experiments, such as blocking NMDA signaling and examining the resulting change in the power spectrum of field potentials. In addition, the contribution of dendritic filtering to the ECoG power spectrum should be further explored (Dehghani et al. 2010; Einevoll et al. 2013).

At the very low-frequency range, below a “shoulder” of 0.1–1 Hz where power is relatively flat, the power spectrum again follows a form close to $P \propto 1/f^2$ (He et al. 2010). Potential generative mechanisms for this low-frequency behavior have recently been explored in a recurrent network model (Chaudhuri et al. 2014). It was found that a recurrent network of rate-based nodes with linear couplings and random connectivity, when poised near criticality (i.e., with balanced excitation and inhibition), could reproduce the low-frequency behavior of the ECoG power spectrum. In such a network, the network recurrent activity produces one or more very slow time constants, whose corresponding “knee” frequencies are below that so far investigated empirically

(0.003 Hz). Moreover, reducing the spatial correlation of the inputs to different nodes resulted in a flattening of the power spectrum, similar to that observed in ECoG and fMRI data during task performance (He 2011; He et al. 2010). Thus, this network naturally converts spatial correlation into temporal correlation, providing support for a previous proposal that decoupling among neuronal groups might underlie the reduction of power-law exponent during task (He 2011).

This low-frequency range of the ECoG activity bears significant resemblance to persistent neural activity (Brody et al. 2003; Major and Tank 2004). As with persistent neural activity, both network and cellular mechanisms may be at play in generating the low-frequency ECoG signals. The effect of different network topology on the power spectrum is an active topic of current investigation. Two recent modeling studies found that network multistability caused by clustered connections or inhibitory neurons is conducive to producing slow fluctuations in population activity (Ho et al. 2012; Litwin-Kumar and Doiron 2012). Potential slow cellular mechanisms include metabotropic glutamate receptors (Zhang and Seguela 2010), endocannabinoid signaling (Carter and Wang 2007), and the cholinergic pathway (Letzkus et al. 2011). The contributions of these different mechanisms to low-frequency ECoG signals should be investigated by future experimental studies.

Some Core Facts About Event-Related Brain Potentials (ERPs)

Speech and its acoustic and linguistic properties essentially evolve in time (Kotz and Schwartz 2010). Therefore, high-temporal-resolution methods such as the electroencephalography (EEG) or magnetoencephalography (MEG) are well suited to trace the temporal unfolding of the speech signal. In particular, ERPs embedded in the EEG permit speech to be monitored with millisecond resolution. By time-locking and averaging ERPs to a large number of specific and similar speech events, responses to acoustic and linguistic properties of these events can tell us how an event is perceived and understood as it occurs. The resulting wavelike pattern consists of an alteration of positive and negative peaks that, when compared to a control condition, leads to the emergence of components that are defined by their polarity (*positive or negative*), by the delay after the onset of an event of interest (*latency*), and by their distribution across the scalp (*topography*). For example, the N400 component is a negative deflection (hence “N”) that peaks around 400 ms post-stimulus onset. Note that while the N400 has a relatively global scalp distribution in the auditory modality, we cannot relate cognitive processes tied to the N400 scalp topography to specific underlying neural sources in the brain. The reason is that EEG activity is oriented orthogonally to the sulcated cortex surface and not to the skull surface. Consequently, ERP patterns recorded at the surface of the skull likely reflect the summation of infinite large numbers of differently oriented sources (*generators*).

What Can ERPs Tell Us About Successful Speech Comprehension?

When listening to speech, our primary goal is to understand what is said. This necessitates the integration of sensory, perceptual, and cognitive processes to ensure successful speech comprehension (Obleser and Kotz 2011). While there has been ample research identifying the neural sources of such integration in neutral (for a review, see Scott and Johnsrude 2003) and emotional speech (for a review, see Schirmer and Kotz 2006), there is less evidence from ERP studies. This is surprising in light of the fact that ERPs monitor the unfolding speech signal from the sensory to the cognitive stage at millisecond resolution and may thus give more precise insight into not only how these processes unfold but also how they are integrated with high temporal precision. Therefore, a number of exemplar ERP studies that have explored the sensory-cognitive interface in speech processing will be reviewed in the following.

A good way to test how early sensory and later cognitive processes in speech processing interact is to study speech in noise. In principle there are at least three sources of noise that can impact successful speech comprehension: noise (i) in the environment, (ii) in the hearing system, and (iii) in the speech signal itself. All three types of noise are considered to disrupt the acoustic/phonetic interface and consequently successful lexico-semantic integration (e.g., Boulenger et al. 2011). A number of ERP investigations have therefore systematically manipulated speech signal quality to look at its consequences on lexico-semantic integration and its impact on successful speech comprehension. In this research two ERP components feature prominently: the N100 and the N400.

Two Components of Interest: N100 and N400

Early ERP components such as the *N100* have been linked to the physical properties of a stimulus and are considered to reflect early obligatory sensory processing (e.g., Luck 2005;

Steinschneider and Dunn 2002). In audition the N100 is considered to encode a sound's onset (e.g., Martin et al. 2008) and to index early perception formation (e.g., Näätänen 2001). It is also attuned to task demands in speech processing (e.g., Bonte et al. 2009; Obleser et al. 2004; Poeppel et al. 1996 for N100m magnetoencephalographic evidence) and the degradation of the sound signal (Miettinen et al. 2010).

N400 research looks back onto a long tradition and has tested semantic anomalies (whether a word fits into a sentence context or not; e.g., Kutas and Hillyard 1980), semantic cloze probability (how likely a word fits a sentence context; e.g., Kutas and Hillyard 1984), context manipulation (how expected a word is in a sentence context; e.g., Van Petten and Kutas 1990), and semantic priming (does a preceding word facilitate the processing of a following word; e.g., Holcomb 1988) in word lists and sentence paradigms in both the auditory and visual modalities. A common viewpoint is that a rise in N400 amplitude reflects the effort of how successfully lexico-semantic integration has taken place (Chwilla et al. 1995; Van Berkum et al. 1999; Friederici 2002; for recent comprehensive reviews, see Lau et al. 2008; Kutas and Federmeier 2011). As such, any modulation of the N400 amplitude, latency, or topography as a function of speech quality is an excellent marker of how alterations of acoustic/phonetic speech properties affect the outcome of lexico-semantic integration and, consequently, successful speech comprehension.

Some Exemplar ERP Investigations of Speech Comprehension

Aydelott et al. (2006) acoustically degraded the speech signal by utilizing a 1-kHz low-pass filter, thereby perceptually changing it. Further, the effect of degradation on lexico-semantic integration was tested on target words that either semantically matched or mismatched a given sentence context. Thus, the ease of lexico-semantic integration was tested by (i) contextually driving semantic expectancy and (ii) manipulating the signal quality of the sentence context. Results revealed

that the N100 response to target words in degraded speech context was enhanced. In addition, the N400 effect (e.g., the difference in amplitude rise to matching and mismatching target words in a sentence context) was reduced in degraded speech when compared to non-degraded speech. The authors concluded that acoustic degradation of the speech signal affects both early perceptual (N100) and later lexico-semantic integration processes (N400). However, the authors did not further address how early and late degradation effects relate to each other. In an attempt to mimic real-life noise situations, *Sivonen et al. (2006)* altered the beginning of sentence final high- and low-cloze probability words by overlaying half of the sentence final words with a cough (short or long) that reduced the phonetic information of the word. Long but not short coughs elicited a larger N100 response to high-cloze probability words in continuous speech. Even though coughs disrupted early phoneme detection, target words were recognized. While there was no N400 amplitude difference for low-cloze compared to high-cloze probability words when words were presented in a noise condition, the onset of the N400 was delayed indicating some difficulties in lexico-semantic integration. The authors suggested that when semantic context is strong enough, incomplete phonemic information can be compensated (e.g., a cough overlaying phonemes).

Obleser and Kotz (2011) used spectrally degraded speech (*Obleser and Kotz 2010*) by applying a noise-band vocoding algorithm that alters the degree of speech intelligibility (*Shannon et al. 1995*). By varying the cloze probability of sentence final words, they tested how small semantic changes in a sentence context affect speech comprehension when the speech signal is compromised. Next to the expected modulation of the N400, the authors reported an early sensory-driven N100 response to speech signal quality at sentence onset. Both the N100 amplitude and latency responded to the degradation strength of the speech signal (strong speech signal degradation led to largest N100 rise and peak). Most importantly, the degree of speech intelligibility significantly impacted the degree

of lexico-semantic integration in the case of low-cloze probability final words. The more intelligible the speech signal, the better the response to unexpected target words in a given sentence context. Therefore, these results clearly show that early sensory-driven effects interact with lexico-semantic integration (for more information on induced oscillatory brain activity, see *Obleser and Kotz 2011*).

A further study by *Boulenger et al. (2011)* tested whether temporally reversing (altering the temporal properties of speech while keeping spectral properties intact) the signal quality of a sentence final word affects how a high-cloze or a low-cloze probability word is integrated into a sentence context. Again, the core of the investigation was to find out how alterations of the speech signal affect lexico-semantic integration. The authors reported early fronto-central negativity in response to target words independent of the degree of temporal reversal (e.g., how much of the speech signal was temporally altered) and cloze probability. This early negativity was spatiotemporally comparable to a mismatch negativity (MMN) recorded in the same participants in an auditory oddball (detection of syllable deviance in temporally reversed speech) in a stream of standard syllables (temporally non-reversed speech). In line with an MMN interpretation that links this component to an automatic and fine-tuned discrimination auditory response mechanism (e.g., *Näätänen 2001*), the authors consider this interpretation also valid in auditory speech comprehension, that is, the MMN response is similar to sinusoidal sound or speech sounds. When looking at the effects of time reversal on lexico-semantic integration, the authors observed an interaction. The degree of temporal reversal (low rather than high reversal) reduced the N400 amplitude response to low-cloze probability words at fronto-central electrode sites. The authors conclude similar to previous accounts that early acoustic/phonetic information interacts with lexico-semantic integration to ensure successful speech comprehension.

Strauß and colleagues (Strauß et al. 2013) pushed forward the investigation of speech intelligibility (three levels of degradation) and

lexico-semantic expectancy. The authors asked the critical question which one of the two factors supporting successful speech comprehension drives the interaction. In other words, is it the bottom-up sensory information or the top-down lexico-semantic information that drives the interaction? The extent of lexico-semantic expectancy in sentence context was varied by manipulating the context strength as well as the cloze probability of the critical word. The results showed that the N400 response to both high- and cloze probability words in a strong sentence context did not differ when speech was intelligible. However, when speech was moderately degraded, only high-cloze probability words in a strong sentence context revealed a decrease in N400 amplitude. This indicates that perceptual constraints may critically impact how context can influence lexico-semantic integration.

In summary, the current evidence on how early sensory and late cognitive processes interact to ensure successful speech comprehension appears to depend upon two processing streams, that is, a bottom-up sensory one and a top-down contextual one. Clearly future research will have to show how task- and/or stimulus-driven demands engage bottom-up or top-down processing streams during successful lexico-semantic integration in speech comprehension.

Definition

Bayesian analysis of electrophysiological data refers to the statistical processing of data obtained in electrophysiological experiments (i.e., recordings of action potentials or voltage measurements with electrodes or imaging devices) which utilizes methods from Bayesian statistics. Bayesian statistics is a framework for describing and modeling empirical data using the mathematical language of probability to model uncertainty. Bayesian statistics provides a principled and exible framework for combining empirical observations with prior knowledge and for quantifying uncertainty. These features are especially useful for analysis questions in which the dataset sizes are small in

comparison to the complexity of the model, which is often the case in neurophysiological data analysis.

Detailed Description

Overview

The Bayesian approach to statistics has become an established framework for analysis of empirical data (Gelman et al. 2003; Spiegelhalter and Rice 2009). While originating as a subdiscipline of statistics, Bayesian techniques have also become associated with the field of *machine learning* (Bishop 2006; Barber 2012). Bayesian statistics is well suited for the analysis of neurophysiological data (Brown et al. 2004; Kass et al. 2005; Chen 2013; Linderman and Gershman 2017): It provides a principled framework for incorporating a priori knowledge about the system by using *prior distributions*, as well as for quantifying the residual (or *posterior*) uncertainty about the parameters after observing the data. For many analysis questions in neurophysiology, one needs to make inferences based on datasets which are small in comparison to the dimensionality or complexity of the model of interest. First, this makes it important to *regularize* the parameter estimates such that they favor explanations of the data which are consistent with prior knowledge. The use of priors also makes it possible to automatically control the complexity of the model inferred from data. Second, the fact that data sizes are small also implies the need to quantify and visualize to what extent model parameters are well constrained by the data. Third, in Bayesian statistics model, parameters are themselves treated as stochastic variables. This provides means of defining richer models by using simple models as building blocks of hierarchically defined models. Fourth, Bayesian statistics provides powerful machinery for dealing with the presence of unobserved processes in the model (so-called latent variables), which are ubiquitous in neurophysiological applications, e.g., arising from internal states or inputs that cannot be measured directly.

In Bayesian statistics, one starts by writing down a probabilistic model $P(Y|\theta)$ of how data Y collected in an experiment are related to an underlying parameter θ . Regarded as a function of θ , $P(Y|\theta)$ is sometimes referred to as the *likelihood*. Prior knowledge about the possible values of θ is encoded by a *prior distribution* $P(\theta)$. Taken together, the prior and the model $P(Y|\theta)$ define a *generative model* of the data – one models the process of data generation as first picking a set of parameters from $P(\theta)$ and then data as being generated from the likelihood model $P(Y|\theta)$. In *Bayesian inference*, one then tries to invert this process: Given empirical data Y , which values of θ are consistent *both* with Y and with the prior assumptions encoded in $P(\theta)$? The trade-off between prior and likelihood will be determined by the amount of available data: For small dataset sizes, the prior will have a strong influence, but for large datasets, the likelihood term which depends on the observed data will dominate. Thus, use of prior distributions can be seen as a form of *regularization* which protects the model against *over fitting* to the observed data.

The *posterior distribution* $P(\theta|Y)$ is calculated via Bayes rule:

$$P(\theta|Y) = \frac{P(Y|\theta)P(\theta)}{P(Y)}. \quad (1)$$

The posterior distribution $P(\theta|Y)$ can then be used to make statements about the parameter values θ . For example, the *posterior mean* $E(\theta|Y) = \int \theta P(\theta|Y) d\theta$ is often reported and visualized in analyses of neurophysiological data as a *point-estimate* of the parameters. In addition, the posterior distribution also gives insight into which properties of θ are well or less well constrained by the data. If, for example, the posterior variance $\text{Var}(\theta|Y)$ is small, this implies that the posterior distribution is concentrated around the posterior mean and thus that θ is well constrained by the data. In general, Bayesian estimators are derived from the posterior distribution, and the focus of Bayesian approaches is always to characterize the distribution of parameters θ *given a particular dataset*. This is in contrast to classical

(or frequentist) statistical approaches, which generally focus on making statements about what will happen – or what is unlikely to happen – if one repeatedly sampled datasets *given a particular parameter setting*.

The denominator $P(Y)$ in Eq. (1) has to be such that the posterior distribution is normalized, i.e., $P(Y) = \int P(Y|\theta') P(\theta') d\theta'$. As $P(Y)$ is the likelihood of the data after marginalizing out (i.e., integrating) the parameters θ , $P(Y)$ is sometimes referred to as the *marginal likelihood* or *evidence*. The evidence provides an estimate of how likely the observed data are for a given model and prior. It is a useful quantity for setting so-called hyper parameters as well as for calculating *Bayes factors*. A Bayes factor is the ratio of the marginal likelihoods of two models and can be used for hypothesis testing and model selection, i.e., for deciding which of two possible models provides a better explanation of some observed data Y (Gelman et al. 2003; Spiegelhalter and Rice 2009). While the use of Bayes factors is gaining popularity in the field of neuroscience, publishing conventions imply that the majority of statistical reporting of results in neurophysiological studies is based on classical, frequentist tests and definitions of p-values.

Example: Receptive Field Estimation

We illustrate the utility of Bayesian approaches for neural data analysis using the example of receptive field estimation for stochastic stimuli using linear models. In a linear encoding model (Paninski et al. 2007), it is assumed that mean firing rate $\mu(s)$ of a neuron in response to a given D -dimensional stimulus can be modeled as being a linear function of the stimulus, $\mu(\mathbf{s}) = \sum_{i=1}^D \theta_i s_i$. In the simplest case, the variability around the mean response is then assumed to be given by a Gaussian distribution, $Y = y|s \sim \mathcal{N}(\mu(\mathbf{s}), \sigma^2)$ with variance σ^2 . The parameter vector θ is called the receptive field, and one tries to estimate θ from the responses $y_1 \dots y_n$ of the neuron to multiple stimuli $\mathbf{s}_1 \dots \mathbf{s}_n$. In classical approaches, one would not place any prior distribution on the values of the parameters θ , and this approach would yield receptive field estimates which *over*

Electrophysiology Analysis, Bayesian, Fig. 1 Illustration of a Bayesian approach for estimating receptive fields (RFs). (Modified, with permission, from Park & Pillow, Plos Computational Biology, 2012 (Park and Pillow 2011)). (a) Spatiotemporal RFs of neurons in primary visual cortex. A light pixel indicates that the neuron is excited by a dark stimulus at a given spatiotemporal position, a dark pixel that its firing is suppressed, gray that its firing rate is not modulated. **ML**, RFs estimated using maximum likelihood (i.e., with a “non-Bayesian” approach) using 1, 2, or 4 min of data; **ridge**, RF estimated

with a simple prior that favors solutions with small weights; **localized**, RFs estimated with Bayesian method developed by Park and Pillow which incorporates the prior knowledge that receptive fields are localized and smooth. Localized estimator achieves better receptive field estimates (as indicated by a cross-validation error metric, red numbers). (b) Advantage of localized estimator persists across different dataset sizes. (c) On average, the non-Bayesian method (ML) requires five times more data than localized estimator to achieve a similar cross-validation error

fit and therefore give noisy estimates, especially for small datasets (see Fig. 1a, left column).

In Bayesian approaches one places a prior distribution $P(\theta)$ on θ . A popular choice for $P(\theta)$ is to choose multivariate normal distribution $P(\theta) \sim \exp\left(-\frac{1}{2}\sum_{i,j}\theta_i\theta_jQ_{ij}\right)$ on θ , where Q is the inverse-covariance matrix of the distribution and different choices of Q correspond to different priors. Q is sometimes chosen to be proportional to an identity matrix. In this case, the Bayesian estimate of θ penalizes solutions for which the square deviations $\sum_j\theta_i^2$ are big. However, as this simple prior does not capture well the structure of receptive fields, it only yields slightly improved estimates (Fig. 1a, middle column). It has generally been assumed that receptive fields are smooth and localized, and covariance matrices which reflect these properties have been developed (Sahani and Linden 2003; Park and Pillow 2011). Figure 1b, c shows that using the Bayesian approach developed by Park and Pillow (which

favors solutions that are localized and smooth) yields receptive field estimates which have superior quality to those obtained using maximum likelihood and which are identifiable on smaller dataset sizes. It is worth noting this prior (and any appropriately constructed Bayesian prior) only *favors* but does not *enforce* receptive fields which are consistent with its assumptions and therefore would still leave open the possibility of being “overruled” if the data provide strong evidence for a solution violating the assumptions.

Algorithmic Challenges

One of the key challenges and practical drawbacks of Bayesian statistics is the fact that computation of the posterior distribution $P(\theta|Y)$ is often hard. Exact solutions are only available in a small number of cases (e.g., when the likelihood of the model is in the exponential family and the prior distribution is *conjugate* to the likelihood (Gelman et al. 2003)), but not for most models

of interest in neurophysiological data analysis. Therefore, in general, approximate methods have to be used to characterize the posterior distribution and its properties (Chen 2013).

Approximate methods can be broadly characterized as being either *deterministic* or *stochastic*. In deterministic approximations, the posterior distribution is approximated by a distribution which has a simpler functional form. In general, numerical optimization is used to find an approximating distribution which is similar to the true posterior. Various approaches exist for finding a “good” approximation, such as the Laplace approximation, expectation propagation, variational inference, and stochastic variational inference, which make it possible to apply these techniques in big data scenarios (Bishop 2006; Hoffman et al. 2013; Blei et al. 2017).

In stochastic (or *Monte Carlo*) methods, the posterior distribution over model parameters is approximated by a set of samples drawn from the posterior. Sampling algorithms are used to generate samples from the posterior distribution $P(\theta|Y)$, and these samples can then be used to perform analyses such as calculating the mean and other moments of the distribution or computing its marginals. While Monte Carlo methods are typically more flexible than deterministic approximations, sampling algorithms such as *Markov Chain Monte Carlo* methods can be computationally intensive (Kass et al. 1998; Gelman et al. 2003; Cronin et al. 2010).

Example Applications

Bayesian statistical methods have been used extensively on a wide range of analysis questions within neurophysiology, including the following examples:

Neural characterization: To describe how neural spiking activity depends on external stimuli, on its own spiking history, as well as on the activity of other neurons, Bayesian methods can be used to estimate receptive fields (Sahani and Linden 2003; Gerwinn et al. 2010; Park and Pillow 2011), tuning curves (Cronin et al.

2010), and spike-history filters (Paninski et al. 2007).

Spike sorting and detection: Inference in hierarchical Bayesian models has been used to extract putative spikes of single neurons from extracellular recordings (Wood et al. 2006) or calcium measurements (Vogelstein et al. 2009; Speiser et al. 2017).

Stimulus reconstruction and decoding: Bayesian time series models have been developed, to reconstruct external stimuli and behavior from population activity or to decode intended movements for brain-machine interface applications (Wu et al. 2006; Gerwinn et al. 2009).

Estimation of information-theoretic quantities: Priors over histograms have been proposed in order to reduce the bias in estimating information-theoretic quantities such as entropy or mutual information (Nemenman et al. 2004; Archer et al. 2012).

Functional connectivity across brain areas: Functional connections across brain areas have been estimated with a range of different Bayesian approaches. In particular, *dynamic causal models* have enjoyed popularity especially for modeling fMRI and EEG data (Marreiros et al. 2010).

Electrotonic Length, Formulas and Estimates

William R. Holmes

Department of Biological Sciences, Ohio
University, Athens, OH, USA

Definition

The electrotonic length of a cylindrical neurite is its physical length divided by its space constant. The electrotonic length of a dendritic tree is estimated with formulas that assume the dendritic tree can be approximated as an equivalent cylinder.

Detailed Description

Rall showed that the complex branched morphology of a dendritic tree can be reduced to an equivalent cylinder given a certain set of assumptions (see entry ► [“Equivalent Cylinder Model \(Rall\)”](#)). An important property of the equivalent cylinder is its electrotonic length, L , which equals the physical length of the cylinder, ℓ , divided by λ , the space constant. An estimate of L will tell us how far distal synapses are electrotonically from the soma, and this will tell us whether these synapses can be effective in driving the cell to threshold.

For a cell represented as an equivalent cylinder, Rall (1969) used separation of variables to derive the transient solution for voltage in the cylinder as

$$V(X, T) = \sum_{n=0}^{\infty} B_n \cos\left(\frac{n\pi X}{L}\right) \exp\left[-\left(1 + (n\pi/L)^2\right)T\right]$$

where X is normalized distance along the cylinder, defined by $X = x/\lambda$ (x is physical distance), and T is normalized time, defined by $T = t/\tau_m$ where τ_m is the membrane time constant. The B_n are determined from the initial conditions $V(X, 0)$. For $n = 0$, the exponential part of the solution is just

$\exp(-t/\tau_0)$ where $\tau_0 = \tau_m = R_m C_m$, the membrane time constant. For $n > 0$, the coefficient of t in the exponential term is $[1 + (n\pi/L)^2]/\tau_0$ where again $\tau_0 = \tau_m$. Rall defined the “equalizing” time constants as $\tau_n = \tau_0/[1 + (n\pi/L)^2]$ and let $C_n = B_n \cos(n\pi X/L)$ to simplify the solution to

$$V(x, t) = \sum_{n=0}^{\infty} C_n e^{-t/\tau_n}$$

where we have also changed back from dimensionless variables X and T to the actual variables x and t . The C_n will depend on the initial conditions. If one applies a current pulse or step and then records the voltage decay once this current is turned off, then this voltage decay is described by

$$V(x, t) = C_0 \exp(-t/\tau_0) + C_1 \exp(-t/\tau_1) + \dots$$

The coefficients and time constants can be estimated from the experimental voltage trace by standard curve fitting procedures. In cells that have significant electrical extent, two time constants are usually obtained, although three are sometimes possible. We are particularly interested in the time constants, because we can rearrange the expression for the equalizing time constants above to get the formula

$$L = \frac{\pi}{\sqrt{\tau_0/\tau_1 - 1}}$$

Thus, if we have τ_0 and τ_1 , we can get an estimate of the cell’s electrotonic length $L = \ell/\lambda$. One must be careful to fit as many terms as possible and then determine if adding a term results in a statistically significant improvement in the fit. Also one must make sure that the values of the coefficients, C_i , are all significantly different from 0.

Rall (1969, 1977) noted that many formulas were possible:

$$L_{\tau_0/\tau_1} = \pi/(\tau_0/\tau_1 - 1)^{1/2}$$

$$C_0/V_0 = \tanh(L_{C_0})/L_{C_0}$$

$$L_{C_0/C_1} = \pi/(2C_0/C_1 - 1)^{1/2}$$

$$L_{vc} = \pi/[2(\tau_0/\tau_{vc1} - 1)^{1/2}]$$

$$L_{vc2} = \pi(9\tau_{vc2} - \tau_{vc1})^{1/2}/[2(\tau_{vc1} - \tau_{vc2})^{1/2}]$$

In these formulas, the subscript of L merely distinguishes the different L estimates. C_0 , C_1 , τ_0 , and τ_1 are the first two coefficients and time constants from the general solution given above estimated from the voltage transient at the soma for a current step applied to the soma. The τ_{vc1} and τ_{vc2} represent time constants estimated from the voltage clamp current transient for voltage clamp at the soma. The V_0 in the second formula equals IR_N the product of the applied current and the input resistance.

The first formula is the one recommended by Rall and is the one used most often; it works well for both brief and long current steps. The second and third formulas rely on coefficient estimates that are prone to error because of floating baseline problems caused by voltage-dependent conductances. The fourth formula requires time constants from both current clamp and voltage clamp experiments, but it may be difficult to get both, particularly in small cells. The last formula requires two voltage clamp time constants, but the second is usually too small to be measured accurately.

These formulas have been applied to data in hundreds of studies, and in most cases L estimates have been 1.0 or less. However, problems can arise with these L estimates if cells cannot be approximated well as an equivalent cylinder. In an equivalent cylinder, the τ_1 (and subsequent τ_n) can be interpreted as equalizing time constants over the length of the cylinder, but if the cell has dendrites that end at different electrotonic distances, the actual τ_1 represents equalization along the longest tip-to-tip path in the cell. The hope is that the estimated τ_1 will reflect equalization between

the soma and dendritic tips, but whether or not this happens depends on the values of the coefficients, many of which have very small values. A second problem is soma shunt with electrode penetration. In this case, the formulas will tend to overestimate L . These issues are discussed in length in series of papers by Holmes et al. (1992), Holmes and Rall (1992), and Major et al. (1993a, b).

Embodied Cognition, Dynamic Field Theory of

Gregor Schöner

Institut für Neuroinformatik, Ruhr-Universität Bochum, Bochum, Germany

Synonyms

[Cognition and control](#); [Neural population models for](#)

Definition

The insight that cognition is grounded in sensorimotor processing and shares many properties with motor control, captured by the notion of “embodied cognition,” has been a starting point for neural process models of cognition. Neural Field models represent spaces relevant to cognition, including physical space, perceptual feature spaces, or movement parameters in activation fields that may receive input from the sensory surfaces and may project onto motor systems. Peaks of activation are units of representation. Their positive levels of activation indicate the instantiation of a representation, while their location specifies metric values along the feature dimensions. By ensuring that peaks are stable states (attractors) of a neural activation dynamics, cognitive processes are endowed with the stability properties required when cognition is linked to sensory and motor processes. Instantiations of cognitive processes arise from instabilities that may induce peaks and suppress. Such events may represent detection, selection, or classification decisions. Neural Field models account for classical behavioral signatures of cognition including response times, error rates, and metric estimation biases but also link to neurophysiological correlates of behavior like patterns of population activation and their temporal evolution. Robotic demonstrations of Neural Field models are used to establish the capacity of these models to provide process accounts of cognition that may link to real sensory

Elementary Motion Detection

► [Visual Motion Detection in *Drosophila*](#)

information and generate real movement in the physical environments.

Detailed Description

Elementary forms of cognition are the detection and selection decisions that control attention and eye movements but are also the basis for object perception. Committing detected perceptual states into working memory and then long-term memory is a key element of cognition. Serially organized sequences of cognitive states are the basis for cognitive processes. Motor actions require that the initiation, termination, and potentially the online update of planned movements be autonomously generated. Neural Field models of cognition and control provide a neural account for such elementary cognition based on four elements: the spaces that such cognitive processes are about, the activation fields defined over these spaces within which neural representations can be created, the neural activation dynamics that drive neural representations forward in time, and the instabilities that give rise to the elementary forms of cognition. This use of Neural Field models to account for cognition and its sensorimotor grounding has been called Dynamic Field Theory (DFT). DFT is a mathematically formalized conceptual framework for understanding embodied cognition that is linked to neural process modeling but abstracts from some of the specific anatomical and biophysical details of neurophysiology to enable a close link to behavior (Schneegans and Schöner 2008).

Spaces

That cognition is grounded in sensorimotor processes is a central insight that the embodiment perspective on cognition emphasizes (Riegler 2002). In this view, cognition is *about* states of the world that may become linked to cognition through perception or action, but are not dictated by perception and action alone. Even mental imagery, for instance, shares the sensorimotor grounding, though it is decoupled in the moment from actual sensorimotor processes. Neural

accounts for cognition must, therefore, take into account how sensory information may potentially drive cognition, primarily through the sensory cortical and subcortical neural structures. Such accounts must also take into account how motor states are driven from cortical and subcortical structures. Common to both domains of sensation and movement is the observation that they are characterized by continuous dimensions: there are continua of possible percepts and continua of possible motor actions. For instance, the possible percepts of a single moving object form a continuum that may be spanned by the retinal location of the object, the direction of motion, perhaps its speed, or motion in depth. The object may have a color that may vary continuously in hue space, have characteristic texture that may vary along a spatial frequency dimension, and may have a surface curvature that varies continuously. Figure 1 illustrates three of these dimensions. Movements similarly form continua, spanned by movement parameters such as the movement direction, extent, and peak velocity of the end effector in a body-centered reference frame. Much of cognition is embedded in the physical space that surrounds our body, even when it takes such flexible form as positioning a thought at a location in space through a hand gesture. Categories are embedded in feature spaces. While a dog is categorically different from a car, both may be morphed into their many different instantiations.

Embodied Cognition, Dynamic Field Theory of, Fig. 1 *Left:* The possible percepts of a single moving object (filled circle moving as indicated by the arrow) may be spanned by continuous dimensions such as the location of the moving object in the visual array and the direction of motion. *Right:* A neural activation field defined over these dimensions (only two shown here) represents a motion percept as a peak of activation positioned over the location that specifies the seen motion

Even superordinate categories may be embedded in feature spaces by combining the feature dimensions of hierarchically organized attributes (McClelland and Rogers 2003).

Neural Fields

Neural Field models of embodied cognition represent the state outside the nervous system by neural activation patterns that are inside the nervous system. Neural activation, as used in Dynamic Field Theory, is a real number, u , that may both be positive or negative. The link to biophysically detailed accounts of neural activity can be established in multiple different ways (see entries ► “Neural Field Model, Continuum”; ► “Neural Population Models and Cortical Field Theory: Overview”). Critical for the link to behavior is the assumption that only sufficiently positive levels of activation impact on downstream structures and ultimately on motor systems. This is expressed mathematically through a sigmoidal function, $g(u)$, often chosen as $1/(1 + \exp(-\beta u))$, where β is the steepness of this nonlinearity.

A Neural Field is a continuum of such activation variables, one for each location of the represented space. For instance, in Fig. 1, a level of activation represents each possible horizontal position and motion direction of a moving object. The field notion is thus analogous to how fields are used in physics. Peaks of activation are units of representation. Their positive levels of activation imply that they impact on downstream processes. Their location specifies the represented state.

How does a location in a Neural Field acquire the meaning ascribed to it in this interpretation? It is ultimately the connectivity to the sensory or the motor surfaces that determines what a field location “stands for.” In perceptual representations such as the one illustrated in Fig. 1, this would be, for instance, the connectivity from the retina, through simple and complex cells, to motion detectors, anatomically probably located in area MT of the cortex. Field locations thus have a “tuning curve.” Similarly, the forward projection onto the motor system implies a specificity that

could be interpreted as a tuning curve for movement parameters. We know that in the cortex as well as in such subcortical structures as the colliculus and thalamus, tuning curves tend to be broad and overlapping, an indication that broad populations of neurons are activated for any individual perceptual or motor state represented. This fact together with detailed analysis of how strongly all activated neurons contribute to a percept or motor action has given rise to the hypothesis that the activity of small populations of neurons is the best neural correlate of behavior (Cohen and Newsome 2009). DFT is based on the further hypothesis that Neural Fields represent the activity of such small populations of neurons in the higher nervous system that are tuned to particular sensory or motor states. In fact, it is possible to estimate Neural Fields from recorded population activity (Erlhagen et al. 1999). This link to population activity frees Neural Fields from the more literal interpretation prevalent in some neural modeling, in which the activation fields are directly defined over the cortical surface. Instead, the Neural Fields on which DFT is based are organized in terms of the topology of the outer space that is being represented. The two interpretations are aligned where cortical maps are topographic. In other cases, however, topography is violated, such as for the tuning of neurons in motor cortex to the direction of a planned hand movement. The Neural Fields of DFT effectively rearrange neurons so that neighboring sites always represent neighboring states. In fact, strictly speaking, neurons are smeared out across the field dimensions by contributing their entire tuning curve to the representation (Erlhagen et al. 1999).

Neural Dynamics

Neural Field models construe time as continuous to approximate at the population level the discrete, but asynchronous spiking events that individual neurons contribute. Mathematically, the evolution in time of the activation state of a Neural Field is described, therefore, by a differential equation (an integrodifferential equation in the specific

Embodied Cognition, Dynamic Field Theory of, Fig. 2 *Left:* A sigmoidal function, $g(u)$, approaches zero for sufficiently negative values, and a positive constant for sufficiently positive values of activation, u . *Right:* Sufficiently activated sites interact excitatorily with nearby locations (green arrow), stabilizing peaks against decay, and inhibitorily with locations that are further removed (red arrow), stabilizing peaks against unlimited growth

formulation reviewed here). DFT postulates that peaks of activation, the meaningful macro-states of Neural Fields, are stable states and fixed-point attractors of the neural dynamics. This constrains the class of admissible dynamical models. Qualitatively, the neural interactions illustrated in Fig. 2 express these constraints. Excitatory neural coupling among neighboring field sites stabilizes peaks against decay; inhibitory coupling among field sites at longer ranges stabilizes peaks against unlimited growth. In the cortex, similarly tuned neurons are typically excitatorily coupled. Inhibitory coupling, mediated by interneurons, is also prevalent (Jancke et al. 1999).

Amari (1977) analyzed a generic Neural Field model in the limit case in which these neural interactions are dominant and showed that peaks of activation may be attractor solutions under appropriate conditions. This is why that particular model has been used in many Neural Field models of embodied cognition, becoming the workhorse of DFT. For a one-dimensional field, $u(x, t)$, defined over a space, x , the dynamics reads

$$\tau u(x, t) = -u(x, t) + h + s(x, t) + \int c(x - x')g(u(x'), t)dx'.$$

The parameter, τ , determines the overall time-scale of the evolution of $u(x, t)$. The “ $-u$ ” term

provides stability to the dynamics and is a reflection of the intrinsic dynamics of neural populations. The parameter $h < 0$ is the resting level of the field, stable in the absence of input, $s(x, t)$. Interaction integrates over all field sites, x' . Each site contributes to the extent to which activation exceeds the threshold of the sigmoidal function $g(u(x', t))$ with a coupling strength, $c(x - x')$ that is a function of the distance between interacting field sites. For close distances, coupling is excitatory ($c(\text{small}) > 0$), for larger distances, inhibitory ($c(\text{large}) < 0$). The Amari model is a simplification over biophysically more detailed models that, among other approximations, neglects the time delays involved in synaptic transmission and lumps together excitatory and inhibitory neural populations (see entry ▶ “Neural Field Model, Continuum”).

Instabilities

There are two qualitatively different attractor solutions of this equation, which are separated by instabilities. In the subthreshold state, the field activation is below zero everywhere, so that interaction is not engaged. If we neglect small values of the sigmoid and assume that inputs vary only very slowly in time, this attractor solution is given by

$$u_0(x, t) = h + s(x, t) < 0,$$

which tracks slowly varying input, $s(x, t)$, apart from a downward shift by h . When input is zero, $s(x, t) = 0$, this is the resting state of the field.

The other solution is a self-stabilized peak of activation, $u_p(x)$, whose activation level is lifted above the level specified by input, $h + s(x, t)$, through excitatory neural interaction, while outside the peak the field is suppressed below the resting level, h , through inhibitory interaction (Fig. 3). For small levels of input, $s(x, t)$, the subthreshold solution is monostable (top panel of Fig. 3), and for sufficiently large levels of input, the self-excited peak solution is monostable (bottom panel of Fig. 3). When input levels are

Embodied Cognition, Dynamic Field Theory of, Fig. 3 A Neural Field, $u(x)$, over dimension, x , illustrated for three levels of input, $s(x)$ (dashed green line) that increase from the *top* to the *bottom* panel. The subthreshold solution, $u_0(x)$ (dashed blue line), is stable for the two lowest levels of input, and the self-excited peak solution, $u_p(x)$ (blue solid line), is stable for the two highest levels of input. The bistable regime is delimited at high levels of input by the detection instability and at low levels of input by the reverse detection instability

increased, the subthreshold solutions become unstable in the detection instability. When input levels are again lowered, the self-stabilized solutions become unstable in the reverse detection instability. Because the reverse detection instability occurs at lower levels of input than the detection instability, the subthreshold and the self-excitatory solutions coexist bistably in a regime of intermediate levels of input strength. This bistable regime stabilizes detection decisions

hysterically. This is critical, when perceptual states represented by peaks are continuously linked to sensory inputs. In the presence of noise, detection decisions must be stabilized against varying input levels to create coherent perceptual experience. Analogously, movement plans must persist when the input from perceptual or cognitive processes, which induces motor intentions, fluctuates.

Both subthreshold and self-stabilized peak solutions are continuously linked to sensory input. The peak may track, for instance, continuously shifting local input patterns. Moreover, if input strength increases in a graded, time-continuous way, the Neural Field autonomously creates a discrete detection event when it goes through the detection instability. Similarly, if input that supports a self-stabilized peak is gradually reduced in strength, the peak collapses at a critical point through the reverse detection instability. Such discrete events emerge from continuous-time neural dynamics through the dynamic instabilities. This provides a mechanism that is critical for understanding how sequential processes may arise in neural dynamics (Sandamirskaya and Schöner 2010).

With sufficiently strong interaction or when broad inputs or a high resting level pushes activation close enough to threshold, the reverse detection instability may not be reached when the strength of a local input is reduced. In this case, a self-stabilized peak induced by local input remains stable and is sustained, even after any trace of the local input has disappeared. Such self-sustained activation peaks are the standard model of working memory (Fuster 2005). Mathematically, self-sustained peaks are marginally stable. They resist change in their shape but are not stable against shifts of the peak along the field dimensions. This leads to drift under the influence of noise or broad inputs. Such drift is psychophysically real: memory for metric information develops metric bias and increases variance over the timescale of tens of seconds (Spencer et al. 2009). Moreover, sustained peaks may be destabilized by competing inputs at other field locations. Again, this limitation of the stability of sustained peaks matches properties of working

Embodied Cognition, Dynamic Field Theory of, Fig. 4 The attractor states, $u_p(x)$, of an activation field are shown in blue; a bimodal input, $s(x)$, is shown in red. There are two attractor states (solid vs. dashed line), which coexist bistably. Each has a single self-stabilized peak positioned over one of the maxima of input, while activation at the other stimulated site is strongly suppressed by inhibitory interaction. The field states were obtained from simulations of the neural dynamics in which independent Gaussian white noise was added at each field location to probe the stability of the stationary states

memory, which is subject to interference from new items entered into working memory.

If the inhibitory component of neural interaction is sufficiently strong and broad, the Neural Field may enact selection decisions as illustrated in Fig. 4. A self-stabilized activation peak may effectively select one of a number of locations in the underlying space that receive localized input. Typically, the most strongly stimulated site will be selected, because after input is provided, activation at that site will reach threshold earliest and begins to suppress activation at other locations before these may reach threshold and, in turn, suppress other locations. Inhibitory interaction thus translates a temporal advantage into a competitive advantage. This is the general feature of decision making in Neural Field models (Trappenberg 2008). In the limit case illustrated in Fig. 4, in which two local inputs have the exact same strength, stochastic fluctuations may bias the competition one way or the other by chance. Once a decision has been made, it is stabilized by the neural interaction within the field. As for detection decisions, this is critical when selection decisions are made, while a system is continuously linked to the sensory surface. Which site receives maximal stimulation may fluctuate in time and a simple

“winner-takes-all” rule would lead to random switching among the selection choices.

The resistance to change is also a reason, while selection decisions are typically made in response to a transient in the input stream. Once locked into a decision, a Neural Field is not open to change, unless the differences in input strength become very large and the selection instability moves the system from a bistable or multi-stable regime to a monostable regime in which only one selection decision is stable. Such resistance to change can be observed as change blindness in which observers fail to detect a change in an image (Simons and Levin 1997). Normally, when an image changes in some location, the visual transients in the sensory input attract visual attention and help detect the change. That transient signal may be masked by turning the entire image off and then turning the locally changed image back on. Observers are blind to change when transients are masked this way, unless they happen to attend to the changed location. Because sensory inputs in the nervous system are typically transient in nature, the mechanism for making selection decisions in DFT is normally engaged by change, so that change detection in the absence of a masking stimulus may also be understood within DFT (Johnson et al. 2009).

The interplay between detection and selection instabilities brings to light a further facet of Neural Fields that provides a bridge to the emergence of categories from the underlying continuous representations. The limit case of a completely homogeneous field, in which all sites have the same dynamic properties, is an idealization, of course. It is easy to break such homogeneity, for instance, by learning processes. In the simplest case, locations at which activation peaks have frequently been induced may acquire higher resting levels, a learning mechanism sometimes used in connectionist models that invoke a bias term and termed the “memory trace” in DFT (Schneegans and Schöner 2008). Hebbian learning may similarly reshape the connections from a cortical surface and induce inhomogeneous levels of activation (Sandamirskaya 2014). Such inhomogeneities may be amplified in Neural Fields by the detection

instability into macroscopic decisions! In the extreme case, an inhomogeneous subthreshold solution may be made unstable by a perfectly homogeneous input, which may be construed as an increase of the resting level, h , that pushes the field over the threshold. The location that first reaches threshold self-excites while at the same time suppressing activation everywhere else. As a result, a self-stabilized peak will arise at that location, in a sense, out of nowhere, because there was no localized input that specified the state that the Neural Field should instantiate. The input that induces a detection instability will not typically be completely homogeneous. It may favor particular locations in the field. Figure 5 illustrates a field that has a pre-shaped subthreshold state, $u_0(x)$. The pre-shape may have arisen from a learning process in which two field locations were frequently activated. An input, $s(x)$, that drives the field through the detection instability provides a broad boost but also contains a small localized component. The self-stabilized peak that emerges is positioned over the pre-activated location that is closest to the localized input. If the location that receives local input was varied continuously, the self-stabilized peak would continue to be positioned close to one of the two pre-activated locations. In this sense, the field responds categorically to spatially continuous input.

Embodied Cognition, Dynamic Field Theory of, Fig. 5 A Neural Field with a pre-shaped subthreshold solution, $u_0(x)$ (blue dashed line), is driven through the detection instability by an input, $s(x)$ (red solid line), that contains a homogenous boost across the entire field and a small localized contribution. A self-stabilized peak solution, $u_p(x)$ (blue solid line), is induced. Its peak is positioned at the closest location that has prior activation, not the stimulated location

Neural Field Models of Embodied Cognition

Neural Field models have been used within the framework of DFT to account for a large and broad set of experimental signatures of the neural mechanisms underlying embodied cognition. Sensorimotor selection decisions were modeled for saccadic eye movements (Kopeck and Schöner 1995) and infant perseverative reaching (Thelen et al. 2001). Influences of non-stimulus factors were accounted for both for saccades (Trappenberg et al. 2001) and in the infant model. The capacity of Neural Field models to account for the confluence of multiple factors is, in fact, a major strength of the approach. An exhaustive account of the influence of many different task and intrinsic factors on motor response times was foundational for DFT (Erlhagen and Schöner 2002). That model also accounted for the time course of movement preparation as observed in the timed movement initiation paradigm. The same model was linked to neural population data from motor and premotor cortex (Bastian et al. 1998), and related ideas were used to account at a much more neurally detailed level for spatial decision making (Cisek 2006). The temporal evaluation of population activity in the visual cortex has been modeled using Neural Fields (Jancke et al. 1999), including recent data that assessed cortical activity through voltage-sensitive dye imaging (Markounikau et al. 2010).

DFT has been the basis of a neural processing approach to the development of cognition (Spencer and Schöner 2003) that emphasizes the sensorimotor basis of cognitive development but has reached to an understanding of how spatial and metric memory develops (Spencer et al. 2006) and how infants build memories through their looking behavior (Schöner and Thelen 2006; Perone and Spencer 2013). A Neural Field model of metric working memory has led to predictions that have been confirmed experimentally (Johnson et al. 2009) and included an account for change detection (Johnson et al. 2008). Neural Field models of motion pattern perception (Hock et al. 2003), attention (Fix et al. 2011), imitation (Erlhagen et al. 2006), and the perceptual

grounding of spatial language (Lipinski et al. 2012) illustrate the breadth of phenomena accessible to Neural Field modeling.

Neural Fields can also be used to endow autonomous robots with simple forms of cognition (Bicho et al. 2000). This work has shown how peaks of activation may couple into motor control systems, an issue first addressed in Kopecz and Schöner (1995). Robotic implementations of the concepts of DFT have generally been useful demonstrations of the capacity of Neural Fields to work directly with realistic online sensory inputs and to control motor behavior in closed loop. Robotic settings have also been useful to develop new theoretical methods that solve conceptual problems. A notable example is the generation of serially ordered sequences of actions (Sandamirskaya and Schöner 2010). Because the inner states of Neural Fields are stable, they resist change. Advancing from one step in a sequence to a next requires, therefore, the controlled generation of instabilities, the release a previous state from stability, and enabling the activation of the subsequent state. The innovative step in (Sandamirskaya and Schöner 2010) was to use a representation of a “condition of satisfaction” that compares current sensory input to the sensory input predicted at the conclusion of an action. This concept has since been used in a variety of models that generate autonomously sequences of mental events. A robotic example is the autonomous acquisition of a scene representation from sequences of covert shifts of attention (Zibner et al. 2011).

Ongoing work in Neural Field modeling of embodied cognition advances on three fronts. On the one hand, the elementary forms of cognition must be integrated into the more complex dynamics of movement generation, coordination, and motor control (Martin et al. 2009). This entails dynamically more complex attractor states including limit cycles, as well as understanding how motor control in closed loop may interface with the population representations modeled by Neural Fields. On the other hand, a systematic push from embodied toward higher cognition (Sandamirskaya et al. 2013) ultimately aims at an understanding of all cognition in neural

processing terms. Such an account faces the challenge of how to reach the power of symbol manipulation while maintaining the grounding in sensory and motor processes. Finally, Neural Field modeling needs to interface more closely with neural mechanisms of learning (Sandamirskaya 2014).

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling

Benjamin Scholl and Nicholas J. Priebe
Section of Neurobiology, The University of Texas
at Austin, Austin, TX, USA

Definition

Orientation tuning is a characteristic response property of neurons in primary visual cortex.

Models of orientation tuning describe the transformation of response selectivity from lateral geniculate relay cells, which are not orientation selective, to neurons in layer 4 of the primary visual cortex. These models aim to constrain and identify the neural circuitry underlying this canonical transformation in the representation of the visual world.

Detailed Description

Introduction

The overarching goal of systems neuroscience is to explain how the sensory inputs we receive are integrated to generate appropriate behaviors. One method of achieving this goal is to study the mechanisms underlying a single computation and build models which may be applied more generally. Computations performed by the cerebral cortex are amenable to this approach due to the relative uniformity of cortical circuitry. Not only does mammalian cerebral cortex contain a common set of neuron cell types with a similar lamination pattern, but it contains a common pattern of neuronal circuitry that processes sensory, motor, and planning-related information. We focus here on a specific computation performed in the visual cortex, orientation selectivity, because this response property is found in primary visual cortex of all mammals in which it has been studied and also because its emergence does not depend on a specific circuitry in visual cortex, as rewiring visual inputs to other portions of the cerebral cortex also yields orientation-selective responses (Sharma et al. 2000). By studying this single property, we therefore hope to gain access to the general computation performed by the cerebral cortex.

In the visual system, sensory information is initially transduced from photons to electrical potentials by retinal photoreceptors. From the photoreceptors, incoming visual information undergoes a number of transformations within the laminar series of neurons in retina, ultimately progressing to retinal ganglion cells, which constitute the retinal output. Retinal ganglion cells have circularly symmetric receptive fields with an antagonistic center/surround organization, meaning they are

unselective for the orientation of objects in visual space (Kuffler 1953). In mammals, retinal ganglion cells project to the lateral geniculate nucleus (LGN) of the thalamus, where relay cells in turn send visual information to the first cortical station: the primary visual cortex (V1). While the receptive field profiles of both retinal ganglion cells and their target LGN relay cells are circularly symmetric, V1 neurons are sensitive to several complex visual stimulus attributes, including stimulus orientation, direction, and binocular disparity (Hubel and Wiesel 1962; Pettigrew et al. 1968; Ohzawa and Freeman 1986). In many cases this selectivity is exquisite: V1 neurons may not respond to visual stimulation at all unless the stimulus features specifically match the neuron's preference. A prime example of this selectivity is the orientation selectivity of V1 neurons: a bar of light oriented along one spatial axis might evoke a robust spiking response in a visual cortical neuron, but the same bar oriented along the orthogonal spatial axis would evoke no response. Following the discovery of orientation tuning in V1 neurons, numerous models have been developed to explain its emergence. We begin by describing the initial proposal to describe orientation tuning, the Hubel and Wiesel feedforward model, as well as the successes and failures of this model in describing orientation tuning in V1.

The Feedforward Model of Orientation Tuning

When Hubel and Wiesel first described cortical orientation selectivity (1962), they proposed a simple and elegant model to explain its emergence, a model which continues to be a reference point for computational models of cortical processing. In their model, neurons in layer IV of the cortex, which receive the bulk of the direct input from thalamic relay cells (Hubel and Wiesel 1962; Gilbert 1977; Bullier and Henry 1979), become orientation selective through the convergence of multiple LGN relay cells (Fig. 1). Thalamic relay cells are themselves generally unselective for orientation since they have circularly symmetric receptive fields. Hubel and Wiesel hypothesized that multiple LGN relay cells

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling, Fig. 1 Hubel and Wiesel feedforward model. LGN relay cell receptive fields spatially aligned along one axis form the basis of the receptive field of a single V1 simple cell (Adapted from Hubel and

Wiesel (1962)). A stimulus oriented along this axis activates all LGN cells simultaneously, generating a large synchronous spiking response. The orthogonal stimulus activates the LGN cells asynchronously, producing a temporally uncorrelated spiking response

with spatially offset receptive fields along a single axis in visual space could converge onto a target cortical cell (Fig. 1). In this way, a visual stimulus oriented along the axis of the spatial offset activates the afferent LGN relay cells simultaneously and produces a large synaptic input onto the recipient simple cell (Fig. 1).

This simple model for cortical orientation selectivity predicts that the relative timing of LGN relay cells is an essential component for the generation of orientation selectivity. Because LGN neurons have circular receptive fields, they respond equally well to all orientations, but their relative timing will vary with stimulus orientation: the spiking responses of LGN relay cells will be nearly simultaneous when an oriented stimulus is presented at the target V1 neuron's preferred orientation but will be spread out in time, or asynchronous, for the orthogonal orientation (Fig. 1).

The elegance of this model lies in the feedforward nature of the systematic transformation of visual information from LGN relay cells to V1: the only requirement being spatial organization of converging excitatory thalamocortical afferents. There is substantial evidence supporting this simple feedforward model. Layer 4 of the

primary visual cortex is composed of neurons which receive direct thalamocortical input (Hubel and Wiesel 1962; Gilbert 1977; Bullier and Henry 1979; Hirsch and Martinez 2006; Martinez et al. 2006; Ferster et al. 1996; Ferster and Lindström 1983). These neurons, called simple cells, have receptive fields composed of oriented and segregated subregions, each giving exclusively ON or OFF responses (response to light onset/dark offset or light offset/dark onset). The LGN relay cells that provide direct input to target simple cells have receptive fields that overlap in spatial position and polarity (Reid and Alonso 1995; Tanaka 1983). Further, inactivation of the cerebral cortex does not disrupt orientation tuning of synaptic input onto simple cells (Ferster et al. 1996; Chung and Ferster 1998; Jagadeesh et al. 1997). These results support, at least in part, the original proposal by Hubel and Wiesel for the generation of cortical orientation selectivity.

Failures of a Simple Feedforward Model

Despite success in describing V1 orientation selectivity, the feedforward model fails to capture

a number of key response properties of cortical neurons. These failures have driven the field to propose a number of alternative hypotheses for the generation of orientation selectivity. The first response property challenging the feedforward model is contrast-invariant orientation tuning (CIOT) (Alitto and Usrey 2004; Sclar and Freeman 1982; Skottun et al. 1987; Troyer et al. 1998; Finn et al. 2007). Despite large changes in stimulus contrast, the orientation tuning width of cortical neurons is largely invariant (Fig. 2). CIOT poses a challenge to the feedforward model because as stimulus contrast increases, the overall activity of relay cell afferents also increases. Because the overall synaptic input to V1 neurons increases with stimulus contrast, the range of orientations evoking a response, and thus the tuning width, should also increase (Fig. 2). A second challenge to the feedforward model is the significant discrepancy between the orientation tuning of individual simple cells based on the response to bars or grating stimuli and the predictions of orientation selectivity based on receptive field maps (Volgushev et al. 1996; Gardner et al. 1999). Receptive field maps, which form the feedforward model basis for how orientation selectivity emerges, systematically underestimate the tuning width of neurons to bars and gratings (Fig. 2). The third challenge to the feedforward model lies in the observed suppression between orientations, known as cross-orientation suppression. Two stimuli of orthogonal orientations (i.e., preferred and orthogonal) induce a suppression of spiking responses in cortical neurons (Allison et al. 2001; Bishop et al. 1973; DeAngelis et al. 1992; Morrone et al. 1982) (Fig. 2). The feedforward model does not include any interaction between neurons tuned to different orientations, so it has been unclear how this suppression would emerge (Fig. 2). A final challenge to the feedforward model is the observed effects of blocking cortical inhibition. Blocking cortical inhibition using bicuculline decreases orientation selectivity, even at concentrations that do not dramatically increase excitatory responses (Sillito 1975; Crook et al. 1997; Hata et al. 1988) (Fig. 2). The feedforward model, however, does not include any role for inhibition, predicting little change in

orientation selectivity following the blockade of the inhibition (Fig. 2).

To account for these response properties that do not necessarily emerge from Hubel and Wiesel's original feedforward model, four primary classes of models have been proposed. It has been argued that orientation tuning arises primarily from intracortical networks, arises from a combination of feedforward mechanisms and cortical inhibitory components, arises from feedforward mechanisms that include known nonlinearities from biophysical properties of individual cortical neurons, and, finally, arises from a feedforward model incorporating LGN relay cell nonlinearities. We will discuss each of these model classes following a top-down approach, starting with a strong emphasis on cortical circuitry and ending with a focus on LGN relay cells.

Models Orientation Tuning Arising from Cortical Circuitry

While the feedforward model does not describe a role for cortical circuitry in the generation of orientation selectivity, the excitatory and inhibitory cortical network may play an important role in the generation of orientation selectivity. One suggestion for how cortical circuitry might contribute to orientation selectivity is that it acts as a ring-attractor network (Ben-Yishai et al. 1995; Goldberg et al. 2004) (Fig. 3a). In ring-attractor networks, orientation selectivity results from the circuitry within cortex, requiring little feedforward selectivity from the convergence of LGN relay cells. Ben-Yishai's model includes all possible cortical interactions (e.g., excitatory-excitatory, excitatory-inhibitory), where the strength of the interactions are related to the differences in the orientation preference of each neuronal pair. Both excitatory and inhibitory inputs share orientation preference, but excitatory inputs dominate between cell pairs with similar tuning, whereas inhibitory inputs dominate between cell pairs with orthogonal tuning. The cortical circuitry generates a ring stable states where all orientations are represented. Only a small bias in external input for orientation pushes the network to converge onto a stable state (Fig. 3a).

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling,
Fig. 2 Failures of the feedforward model. The Hubel and Wiesel feedforward model (*bottom row*) fails to capture characteristics of orientation tuning in actual V1 cortical neurons (*top row*): (1) orientation tuning width varies with contrast (*left*) and

An interesting feature of this model architecture is that it predicts that orientation tuning does not depend on other stimulus features, including the spatial frequency and the contrast of the stimulus, since selectivity is determined by the cortical architecture. In this way, the cortical network represents all orientations, invariant to the contrast of the stimulus.

A similar model of orientation selectivity relying on the cortical network has also been proposed by Somers et al. (1995). As with the Ben-Yishai model, weak orientation preference is provided by the convergence of LGN relay cells, but the cortical circuitry amplifies and sculpts that weak bias into strong orientation tuning (Carandini and Ringach 1997). Intracortical excitation provides the dominant source of excitatory drive, with neurons that share orientation preference strongly interconnected. To maintain sharp orientation tuning and contrast invariance, model simple cells receive a significant inhibitory input. This inhibition comes from inhibitory neurons sharing orientation preference and is required for canceling the weakly tuned excitatory relay cell input. To assure that nonpreferred orientations are quenched by inhibition, the model proposes that inhibitory input onto simple cells is more broadly tuned than excitatory input (Fig. 3b). A nonpreferred

orientation will drive afferent LGN neurons to a cortical excitatory cell, but that weak input is suppressed by inhibition, either from inhibitory neurons that are more broadly tuned than excitatory neurons or from inhibitory neurons with different orientation preferences. In contrast, the preferred orientation drives a weak LGN input amplified by intracortical excitatory circuitry. A related model architecture has also been proposed by McLaughlin et al. (2000), relying on intracortical connectivity to shape orientation selectivity. The McLaughlin model architecture is characterized by an isotropic connectivity pattern for excitation and inhibition instead of the Somers's proposed architecture with broad inhibition. To account for contrast-invariant orientation tuning, this model incorporates large intrinsic fluctuations emerging from sparse connectivity. These fluctuations push the model into a critical state such that contrast-invariant orientation tuning may emerge (Tao et al. 2006).

The proposals by Ben-Yishai et al., Somers et al., and McLaughlin et al. all rely on cortical interactions to generate the shape of the orientation selectivity but still require a weak orientation bias in the input, which could come from the convergence of spatially offset neurons, as originally proposed by Hubel and Wiesel. In contrast,

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling, Fig. 3 Cortical mechanisms of orientation tuning. (a) A ring-attractor network produces cortical orientation tuning independent of stimulus parameters. An attractor network representing all orientations (theta) explores unstable states of activity without external input. A small external input, such as weak orientation selectivity from the LGN (*inset*), pushes the ring into a

stable configuration with neural activity centered around the orientation bias of the input. (b) Orientation tuning curves of different input onto a single cortical neuron in the Somers et al. (1995) model. Weakly tuned LGN excitation is combined with sharply tuned cortical excitation and more broadly tuned inhibition to generate orientation-selective input

Adorján et al. (1999) have proposed a model based purely on an “intracortical hypothesis,” wherein lateral intracortical connections drive *both* initial orientation bias and subsequent amplification without selectivity of thalamocortical inputs. To generate orientation selectivity from cortical mechanisms alone, the authors propose cortical RFs lie along one axis in visual space. Neurons whose RFs fall onto one axis belong to an orientation column and laterally connected by strong excitatory interactions. Such a connectivity anisotropy forms the basis for orientation specificity from incoming retinotopic inputs. Using this initial anisotropy to generate a bias in orientation selectivity, the shape of the orientation tuning curve is sculpted by a convergence of excitatory input amplifying the initial bias and inhibitory input, which is more broadly selective than excitatory inputs, as in the proposal by Somers et al. (1995). This proposal is particularly relevant to the emergence of orientation selectivity in the primate V1. In contrast to cat V1, where orientation selectivity is apparent in layer 4, strong orientation selectivity in primate V1 is only observed in layers that do not receive direct input from relay cell afferents (Hubel and Wiesel 1968; Blasdel and Fitzpatrick 1984; Ringach et al. 2002). In the primate, therefore, it appears that a strong role for cortical circuitry is required to generate orientation selectivity.

Models of Inhibition Sculpting Orientation-Tuned LGN Synaptic Input

A second class of models asks how cortical circuitry, inhibition in particular, might enhance or sharpen feedforward input into V1, but these models rely primarily on the feedforward input to determine selectivity. Importantly, the inclusion of cortical excitation and inhibition allows for these models to express many of the behaviors that are missing the simple feedforward model (Fig. 2).

To account for contrast-invariant orientation selectivity, Troyer et al. (1998) developed a model using both a well-defined and physiologically realistic LGN firing pattern as input to a

cortical network and correlation-based connections between cortical layer 4 neurons. Correlation-based input is defined as the connection probability between neuronal pairs as a function of the degree of correlation (excitatory-excitatory) or anticorrelation (inhibitory-excitatory) between RFs. Receptive fields that are highly correlated are those from neurons sharing both orientation selectivity and a similar pattern of ON and OFF subfields, while anticorrelated receptive fields are from neurons that share orientation selectivity but have the opposite pattern of ON and OFF subfields (Fig. 4a). In this pattern of connectivity, the orientation selectivity for inhibition and excitation share orientation preference but are evoked by the opposite polarity stimulus conditions (Fig. 4a). This relationship between excitation and inhibition is called push-pull.

To solve the problem of contrast invariance, it is important to note that the aggregate LGN input contains two components: (1) an orientation-tuned component and (2) an untuned, contrast-dependent component (Fig. 4b). As contrast increases, the untuned contrast-dependent component of the LGN increases and must be suppressed to preserve invariance. In the Troyer et al. model, inhibitory neurons suppress this untuned component by having different orientation tuning than excitatory neurons. Specifically, these inhibitory neurons respond to all stimulus orientations, providing a suppressive signal related to stimulus contrast. This contrast-dependent inhibition removes the untuned component of the LGN input and preserves orientation selectivity (Fig. 4b and c). LGN excitation and cortical inhibition are combined to generate cortical membrane potential (Fig. 4d), which is then passed through threshold non-linearity to produce cortical spiking responses and CIOT (Fig. 4e).

This model makes several predictions about inhibitory input onto layer 4 V1 neurons. First, inhibitory neurons should have similar RF structure as excitatory neurons in cat layer 4 in order to create the tuned inhibitory component. In fact, several studies have shown this to be the case (Gilbert and Wiesel 1979; Toyama et al. 1981; Martin 1988; Hirsch et al. 1998, 2003). Second, there must exist inhibitory neurons in layer

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling, Fig. 4 Feedforward model with cortical inhibition. (a) Schematic of layer 4 cortical circuit. LGN relay cells innervate both cortical excitatory and inhibitory neurons. Inhibitory neurons provide suppressive input onto excitatory neurons. There are two inhibitory components: an orientation-selective with opposite receptive field phase component generating push-pull and an unselective contrast-sensitive component providing DC

suppression. These are hypothesized to be due to separate neuron populations (Hirsch et al. 2003). (b) LGN excitation exhibits broad orientation tuning and the untuned (mean) component increases with contrast. (c) Cortical inhibition exhibits broad tuning and increases with contrast for all orientations to suppress untuned LGN component. (d–e) Cortical membrane potential generated from LGN excitation and cortical inhibition is passed through a threshold nonlinearity (blue) to generate spiking responses

4 which provide untuned (unmodulating, phase nonspecific), contrast-dependent responses. Identified inhibitory neurons in layer 4 are generally orientation selective, like their excitatory counterparts, which is contrary to the suggestion in the Troyer model (Cardin et al. 2007). A small proportion of inhibitory neurons have been recorded from that are completely untuned for orientation, and these neurons could provide the required suppression to remove the untuned component of the feedforward input (Hirsch et al. 2003) (Fig. 4a). Following the study by Hirsch et al., a modified version of the original Troyer model was proposed to that included a combination of orientation-tuned and untuned inhibitory neurons. This model also accounts for CIOT (Lauritzen and Miller 2003) (Fig. 4d and e). An additional prediction of Troyer and Lauritzen models is that V1 neurons with direct thalamocortical innervation should have excitatory and inhibitory conductances which are antagonistic in nature. Evidence for this final prediction has been reported in the

synaptic integration of simple cells (Hirsch et al. 1998), direction selectivity of simple cells (Priebe and Ferster 2005), and measurements of conductances underlying orientation tuning (Anderson et al. 2000).

An additional model that has been proposed which relies on the LGN input for orientation selectivity is the proposal by Wörgötter and Koch (1991). They explore a recurrent cortical network composed solely of intracortical inhibition. Although there were no intracortical excitatory connections, both inhibitory and excitatory neurons received the same thalamocortical input. Using this model they test the effects of many different inhibitory connection regimes to supplement the basic Hubel and Wiesel framework: random, sparse, local, circular broad, and cross-orientation input. They found that cross-orientation inhibition was not effective in producing a realistic population of cortical orientation tuning, as an emergent property of the network was an overrepresentation of vertical and horizontal orientations.

A combination of circular broad inhibition (500 μm range) and local, iso-orientation (within column) inhibitory input was able to produce orientation tuning in layer 4. In this way, a weak LGN input was sculpted away leaving highly selectivity orientation tuning. This model is very similar to the framework of Somers et al. (1995) (Fig. 3b), but without contribution of any intracortical excitation. The use of circularly broad and local inhibitory inputs is conceptually similar to models of contrast-set gain control whereby a divisive mechanism integrates over a “normalization pool” to compress responses at high contrasts (Heeger 1992; Geisler and Albrecht 1992).

Models of Biophysical Properties in Cortical Neurons

A third class of models examines how the nonlinear properties of cortical neurons receiving direction thalamocortical input would add onto the original Hubel and Wiesel framework to generate orientation tuning. Unlike the last two model classes, which rely on intracortical interactions to shape tuning, these models compliment the feedforward model with the nonlinear biophysical properties of cortical neurons and the LGN input.

Surprisingly the inclusion of simple, known biophysical properties of neurons along the visual pathway can contribute to the emergence of contrast invariance, tuning profile sharpness, and cross-orientation suppression (Carandini and Ferster 2000; Finn et al. 2007; Priebe and Ferster 2008).

A detailed examination of a purely feedforward Hubel and Wiesel model reveals a problematic mismatch between orientation tuning predictions from an RF map and the actual responses of a given neuron (Gardner et al. 1999; Jones and Palmer 1987) (Fig. 2). One resolution to this issue is that this mismatch is a by-product of the nonlinear transformation of subthreshold membrane potential to action potentials (Priebe and Ferster 2008). To incorporate this nonlinearity models, retain the simple elements of a feedforward mechanism, but pass the aggregate LGN input through a nonlinearity composed of either a threshold followed by a linear function or a power law (Fig. 5, *top*). Measurements of both subthreshold and suprathreshold responses, incorporating this nonlinearity, generate more accurate predictions of spike tuning in V1 simple cells (Bringuier et al. 1999; Carandini and Ferster 2000; Finn et al. 2007; Priebe and Ferster 2008). As predicted from this simple nonlinearity

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling, Fig. 5 Feedforward model with biophysical cortical nonlinearities. Subthreshold membrane potential (V_m) orientation tuning is passed through a static nonlinearity (power law) to generate spiking

responses (*top*). Orientation tuning of spiking output is narrower than LGN input or V_m but still contains untuned component (compare spiking at high and low contrasts at 90°). A contrast-dependent power law (*bottom*) generates contrast-invariant orientation tuning of spiking responses

subthreshold membrane, potential responses are consistently more broadly tuned than spiking responses (Fig. 5) (Carandini and Ferster 2000; Finn et al. 2007; Nowak et al. 2010). Although in some cases, the difference between subthreshold and suprathreshold spatial-temporal RF maps can be entirely explained by a static nonlinearity (Mohanty et al. 2012), simply incorporating this nonlinearity to the output of simple cells falls short of explaining contrast invariance, because as contrast increases, more and more inputs should cross spike threshold, therein increasing tuning width (Figs. 2 and 5).

How could contrast invariance be attained utilizing only nonlinear properties of cortical neurons? Finn et al. (2007) proposed an elegant solution: the relationship between membrane potential and spiking activity depends on contrast. Specifically, they proposed that the threshold nonlinearity is dependent on response variability and this variability is affected by stimulus contrast (Fig. 5, *bottom*). As contrast decreases, variability increases, which increases steepness of the expansive component (Fig. 5, *bottom*). Increased steepness in the expansive component equates to membrane potential fluctuations generating larger spiking responses. A contrast-dependent threshold nonlinearity provides a simple method to scale the transformation of membrane potential inputs into spiking responses. At low contrasts, only membrane potential fluctuations at or near the preferred orientation can elicit spikes. At high contrasts, membrane potential depolarizations are much larger, but since the threshold nonlinearity greatly decreases a neuron's sensitivity to these inputs, only sufficiently large inputs at or near the preferred orientation elicit spikes. In this way, contrast invariance can appear in simple cells without inhibitory input or contribution of intracortical excitation.

Models of LGN Response Properties and Orientation Bias

Thus far, the models examined focus on the cortex, the target of thalamocortical axons, and the site of the emergence of orientation selectivity.

This final class of models proposes alternate solutions for the emergence of orientation selectivity that include the properties of the thalamic relay cells. Here we discuss several models which utilize different aspects of the relay cells to generate orientation-tuned synaptic input onto V1 simple cells. These include synaptic depression of geniculate relay cell axons, trial-to-trial variability in LGN synaptic input, synchronicity of geniculate cell spiking activity, and a radial bias in the selectivity of LGN cells.

Synaptic depression is attributed to the depletion of readily releasable synaptic vesicles in the presynaptic axon terminal. Repeated activation of a single terminal over short timescales can decrease the number of vesicles released, reducing the efficacy of the synapse. As presynaptic LGN spiking activity increases with contrast, so does the effect of synaptic depression on a postsynaptic targets (Markram and Tsodyks 1996; Abbott et al. 1997). As a presynaptic cell fires more action potentials, the efficacy of individual action potentials on the postsynaptic cell decreases (Fig. 6a, *top*). Banitt et al. (2007) measured the effects that synaptic depression would have on a biophysically realistic layer 4 model cortical cell receiving a large number LGN inputs, largely following the Hubel and Wiesel framework. Strong feedforward synaptic depression compressed responses to all different contrasts. In particular, high contrast stimuli were larger and showed broader tuning without synaptic depression of thalamocortical synapses (Fig. 6a, *bottom*). Incorporating the synaptic depression sharpened tuning (Fig. 6a, *bottom*), produced CIOT (Banitt et al. 2007; Carandini et al. 2002). For nonpreferred stimuli, membrane potential depolarizations were too small to evoke spiking responses with synaptic depression, while co-activation of LGN relay cells for preferred stimuli were large enough to evoke spiking activity. Thus, a biophysical feedforward model including synaptic depression generated invariant orientation tuning.

A primary component of the Hubel and Wiesel model is that preferred orientation visual stimuli evoke a synchronous activation of LGN relay cells. Individual layer 4 V1 neurons integrate

Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling, Fig. 6 Feedforward model with biophysical LGN nonlinearities. (a) Synaptic depression of thalamocortical synapses (top) onto layer 4 cortical neurons compresses LGN input and can generate contrast-invariant orientation tuning. (b) Synchronicity of multiple LGN relay cells onto a single cortical neuron can increase orientation selectivity. Synchronous spiking activity, compared to additive activity, generates narrower receptive

fields in cortical neurons. Synchronous spiking activity also creates narrow orientation tuning compared to a simple linear model of LGN spiking input. (c) Circularly symmetric LGN receptive fields are aligned to one axis to generate oriented receptive fields in V1. Incorporating oriented LGN receptive fields to the original Hubel and Wiesel model can generate oriented receptive fields and orientation tuning without a strict arrangement

over 10–100 different LGN relay cells. Any synchrony between the LGN relay cells could play an important role in the generation of V1 orientation selectivity (Fig. 6b, left). Stanley et al. (2012) envisioned two extreme ways in which incoming thalamic spikes might combine to generate spikes in cortical simple cells: through either additive or multiplicative nature. Addition of presynaptic spikes to generate cortical spikes is a linear process, meaning that 1 spike from two relay cells arriving simultaneously would generate 2 spikes in a cortical neuron. Multiplication of incoming spikes would imply that 1 spike arriving simultaneously from 2 relay cells would only generate 1 spike in the postsynaptic cortical neuron. In this way, synchronous activity is represented by multiplicative nature of LGN pairs. Models demonstrate synchronicity could enhance RF elongation and sharpen orientation tuning (Stanley et al. 2012; Wang et al. 2010) (Fig. 6b, right). Varying the “jitter” in relay cell spike arrival times onto the cortical neuron causes significance changes in the membrane potential and spike rate transformation and therefore alters the tuning of downstream

targets. If the degree of relay cell synchrony is linked to contrast, this synchrony could play an important role in the emergence of contrast-invariant orientation tuning (Finn et al. 2007; also see above) (Fig. 6b, right).

Geniculate relay cells, like many sensory neurons in the central nervous system, have variability in their responses to a stimulus. How might this variability play a role in the generation of orientation tuning? Sadogopan and Ferster (2012) measured the contrast dependence of relay cell variability and found that it shares the known contrast dependence of variability of target cortical neurons. They use a biophysical feedforward model of geniculate relay cells innervating a layer 4 simple cell (Fig. 5) to demonstrate that cortical variability could be inherited from the thalamus. Their model contained many linear and nonlinear components, including LGN RF convergence and spatial organization, pairwise correlations in relay cells, variability in LGN spiking responses, thalamocortical synaptic depression, a conductance-based synaptic input onto cortical neurons,

and the nonlinear transformation from conductance to membrane potential. This model was able to capture subthreshold membrane potential responses of cortical simple cells but also demonstrated sharp, contrast-invariant orientation tuning. It should be noted, however, that this model does incorporate several nonlinear properties of geniculate and cortical neurons. Although variability in LGN inputs might be an important factor for generating realistic orientation tuning, this response property most likely arises from a multitude of nonlinear mechanisms.

A final model orientation tuning centers around orientation selectivity of LGN relay cells themselves. Evidence for subcortical orientation selectivity has been observed in carnivores, where orientation biases have been associated with systematic asymmetries of retinal ganglion cell arbors (Boycott and Wässle 1974; Cleland and Levick 1974; Hammond 1974; Levick and Thibos 1980; Leventhal and Schall 1983; Shou et al. 1995). Volgushev et al. (1996) and Vidyasagar et al. (1996) proposed a simple model in which these asymmetries add to the original Hubel and Wiesel framework to generate orientation tuning. In their model, weak selectivity in thalamocortical inputs is combined LGN RF spatial overlap (Fig. 6c). As long as radial biases are parallel to the spatial organization of LGN RFs, then stimuli oriented along that axis should generate a larger synaptic input onto cortical neurons. This selectivity could be further enhanced either by dendritic nonlinearities such as voltage-gated ion channels (Pei et al. 1994; Vidyasagar et al. 1996) or simply through the transformation of membrane potential to action potentials in cortical simple cells.

Concluding Remarks

We have discussed four major classes of models of describing orientation tuning in V1. These include hypotheses that cortical circuitry determines orientation selectivity, inhibition sculpting feedforward excitation generates invariance and other properties, biophysical nonlinearities of cortical neurons are sufficient to generate

orientation tuning, and feedforward LGN input already poses nonlinearities which culminate to generate properties of cortical tuning. It is important to note that many mechanisms of these models are not exclusive, but rather inclusive and communal. For example, network models are not capable of producing invariant orientation tuning with inhibitory contributions. Additionally, biophysical models often contain many overlapping features like synaptic depression. All these biophysical mechanisms are known to exist: synaptic depression is basic property of chemical synapses (Stratford et al. 1996), as is the transformation of membrane potential to spiking activity in cortical neurons (Hodgkin and Huxley 1952). A similar argument can be applied to cortical networks; despite strong focus on strictly feedforward models, it is well known that cortical circuitry is complex and there exist a number of synaptic connections between excitatory and inhibitory neurons. These facts suggest that perhaps all models of orientation tuning reflect the true sensory computation. That is, the mammalian early visual system may have adopted a number of mechanisms which work in tandem to generate orientation tuning (Monier et al. 2003).

Endocrine Cell Function and Dysfunction

Richard Bertram

Department of Mathematics, Florida State University, Tallahassee, FL, USA

Definition

The endocrine system refers to the cells and tissue that release hormones into the blood. Unlike synaptic chemical communication, which is localized to the target cell, endocrine communication is global. The hormones act on other endocrine glands such as the adrenal gland, ovaries, testes, and others, as well as on the heart, kidneys, muscle, and the brain. Mathematical modeling has been used to understand network interactions mediated by the endocrine system, as well as the effects of hormones on single cells.

Detailed Description

Background

Like neurons, many endocrine cells are electrically excitable and release hormones through Ca^{2+} -mediated exocytosis (Stojilkovic et al. 2010). These have been the focus of mathematical modeling and computer simulation to better understand the mechanisms through which the cells operate. Several endocrine cell types are involved in diseases with substantial morbidity and mortality, making them an important target for model-assisted investigation.

The most computational work to date has focused on the endocrine cells located within the pancreas in micro-organs called **islets of Langerhans** and cells in the anterior region of the pituitary gland. There has also been modeling work done on the interaction between endocrine cells of different glands and between an endocrine gland and the brain. However, modeling of the endocrine system is still in its infancy, so there is much potential for future work. Here, we consider two examples. The first illustrates cellular-level

modeling of endocrine cells, and the second illustrates mean-field modeling of interactions between two endocrine glands.

Models of Pancreatic Islets

Islets are clusters of endocrine cells coupled together by gap junctions. They serve as endocrine micro-organs, and the pancreas contains hundreds of thousands of them. An islet consists of glucagon-secreting α -cells, insulin-secreting β -cells, somatostatin-secreting δ -cells, and cells that secrete pancreatic polypeptide. The gap junctions that connect neighboring cells provide electrical coupling among cells of the same type, which has the effect of synchronizing their activity.

Almost all of the computational modeling that has been done on islets has focused on the β -cells. These cells sense the blood glucose concentration, and when the concentration is sufficiently high, they produce a rhythmic pattern of electrical activity called **bursting**, cycles of electrical impulses separated by quiescent periods. Insulin is secreted during the active phase of the burst, which acts on target tissue such as muscle and the liver to take up glucose from the blood and metabolize it. The physiological importance of insulin secretion from β -cells, and the interesting question of how this periodic electrical activity could be produced, prompted Teresa Chay and Joel Keizer to develop the first mathematical model of β -cell electrical activity in 1983 (Chay and Keizer 1983). This model provided key insights into biophysical mechanisms for burst generation and initiated a several-decade-long series of models by them and others for pancreatic β -cells, each differing primarily in the mechanism for burst generation.

A key prediction of the **Chay-Keizer model** is that the intracellular Ca^{2+} concentration should have a sawtooth shape. This prediction was falsified when fura-2 fluorescent dye was used to measure the intracellular Ca^{2+} concentration and it was demonstrated that it has more of a square-wave shape. Other data has continued to drive revisions in the β -cell models. As the models

Endocrine Cell Function and Dysfunction, Fig. 1 Compound bursting oscillations in electrical activity generated by the Dual Oscillator Model

have grown in complexity, they have grown in explanatory capacity.

A good model of islet β -cells should be capable of explaining the 5-min oscillations in the blood insulin concentration that is typical in nondiabetic humans, mice, rats, and dogs. These oscillations correspond to either **slow bursting** or **compound bursting** activity in islets. The latter consists of bursts of electrical bursts (Fig. 1). Both slow and compound bursting oscillations have been observed frequently in isolated islets when the patch clamp technique is used to measure β -cell voltage (rather than a sharp electrode, as was used earlier). A model capable of producing slow and compound bursting oscillations, as well as the faster bursting oscillations often seen in islets, is the **Dual Oscillator Model** (Fig. 2) (Bertram et al. 2004, 2007a).

The first element of this model is an electrical component that also takes care of Ca^{2+} handling. This is a descendent of the Chay-Keizer model, with significant modification, and can account for the fast bursting oscillations often seen in islets. The second element describes a portion of the glycolytic pathway containing the allosteric enzyme phosphofructokinase. The product of this enzyme stimulates the enzyme's own catalytic activity and can produce slow oscillations in glycolytic activity. The third element describes portions of the citric acid cycle and oxidative phosphorylation, both of which occur in mitochondria. In the model, either slow or compound bursting oscillations are produced when the glycolytic subsystem is in an oscillatory state, which results in packaging of electrical activity into episodes. The effect of glycolytic oscillations on the electrical activity is mediated via the

Endocrine Cell Function and Dysfunction, Fig. 2 The three main components of the Dual Oscillator Model and the interaction flow

mitochondrial production of adenosine triphosphate (ATP), which acts on ATP-sensitive potassium ion channels in the plasma membrane. This model is able to account for the different types of bursting observed in islets, the ability of changes in glucose to convert the islet from one type of bursting pattern to another, and the effects of several pharmacological manipulations. Importantly, the model has been used to design experiments and to interpret experimental results in unintuitive ways. See Sherman (2010) and Bertram et al. (2007b) for details.

A Model for Glucocorticoid Pulsatility

Glucocorticoids (cortisol in humans and corticosterone in rats and mice) are released from the adrenal cortex and are key stress hormones that regulate the cardiovascular, cognitive, metabolic, and immunological states of the animal. Like many hormones, glucocorticoids are released in a pulsatile manner. This **ultradian rhythm**, with period of about 1 h, is superimposed on a **circadian rhythm** of glucocorticoid release so that the ultradian pulse amplitude is high during the active period of the animal and low during sleep. It has been demonstrated that the physiological response to a stressor is determined in part by the time of onset of the stressor in relation to the phase of the rhythm (Windle et al. 1998). It has also been demonstrated that glucocorticoid-responsive genes respond differently to pulses of glucocorticoids versus constant application of the hormone (Stravreva et al. 2009).

Endocrine Cell Function and Dysfunction, Fig. 3 Diagram of the stimulatory (arrows) and inhibitory (ball and stick) interactions responsible for the control of glucocorticoid (CORT) release. The effect of corticotrophin (ACTH) has a delay time τ reflecting the time required to synthesize CORT

The network of interactions controlling the release of glucocorticoids is illustrated in Fig. 3. Time of day information is provided by the supra-chiasmatic nucleus (SCN) of the hypothalamus, and information on cognitive and physical stressors is provided by the central nervous system (CNS). A set of neurons in the paraventricular nucleus (PVN) of the hypothalamus receives and integrates this information and then releases the neurohormone corticotropin-releasing hormone (CRH) into portal blood vessels that project to cells of the anterior pituitary gland. Corticotroph cells are stimulated by CRH and in response release corticotropin (ACTH) into the general circulation. This hormone acts on cells of the adrenal cortex to produce and release glucocorticoids (CORT). Because CORT is not stored, but is synthesized only in response to ACTH, there is a time delay between ACTH stimulation and CORT release. Once released, the CORT feeds back onto and inhibits both the CRH-releasing neurons in the hypothalamus and the ACTH-releasing corticotrophs in the pituitary gland.

Computer simulations with a mathematical model demonstrated that the ultradian rhythm in CORT can be produced by the mutual interactions of corticotrophs with adrenal cells (Walker et al. 2010). That is, the rhythm can be generated even with a constant input from the hypothalamus, as long as the strength of that input is in the right range and the time delay is long enough. To demonstrate this, they used a mean-field model with three variables: a = ACTH concentration, r = glucocorticoid receptor availability in the corticotrophs, and c = corticosterone. The variables change in time according to the differential equations

$$\begin{aligned}\frac{da}{dt} &= \frac{p_1}{1 + p_2rc} - p_3a \\ \frac{dr}{dt} &= \frac{(cr)^2}{p_4 + (cr)^2} + p_5 - p_6r \\ \frac{dc}{dt} &= a(t - \tau) - c\end{aligned}$$

where the p_j are parameters. The first equation includes the negative feedback of CORT onto ACTH release (c in the denominator of the first term). The second equation includes the positive influence of CORT on glucocorticoid receptors; the receptor number increases when CORT levels increase. The third equation includes the positive influence of ACTH on CORT synthesis and release. This has an explicit time delay of τ time units, representing the time required for the synthesis of CORT following the receipt of ACTH by the adrenal gland. These equations were constructed in dimensionless form.

Figure 4 shows the results of computer simulations with this model, with parameters chosen as in Walker et al. (2010). In these simulations the CRH level is fixed and is represented by the parameter p_1 . This is initially set at a low value of 10 and no oscillations are produced. Then, at the closed arrow, the CRH drive is increased to 15. This initiates oscillations in CORT (black), as well as oscillations in ACTH (red) that are phase shifted with the CORT oscillations. When the time delay is later decreased from 1.5 to 1 time units (open arrow), the oscillations die out and the system

Endocrine Cell Function and Dysfunction,

Fig. 4 Oscillations in CORT and ACTH due to the delayed positive feedback of ACTH onto CORT production. These oscillations require sufficient drive from the hypothalamus (*closed arrow*) and they die away if the time delay is too short (*open arrow*). All variables are dimensionless

approaches a steady state. Thus, this simple model elegantly demonstrates several important predictions: (1) ultradian oscillations can be generated even if the output from the hypothalamus is held constant at a sufficiently high level, (2) the ACTH oscillations will be phase shifted relative to the CORT oscillations, and (3) oscillations only occur if the time lag between ACTH release and CORT synthesis and release is sufficiently large.

The essential ingredient for rhythm generation in this model is the delayed positive feedback of one component onto its inhibitor. Another model in which this occurs describes a semicircadian rhythm in the secretion of prolactin from pituitary lactotrophs (Bertram et al. 2006). This rhythm occurs during the first half of pregnancy in the rat and, according to the mathematical model, is produced by the delayed positive feedback of prolactin onto the dopamine-secreting neurons of the hypothalamic arcuate nucleus. The dopamine is synthesized in response to prolactin activation with a time delay. Once released into the portal blood vessels connecting the hypothalamus to the pituitary, dopamine acts on lactotrophs and inhibits prolactin secretion, just as CORT inhibits ACTH secretion from corticotrophs.

Environmental Sound Perception: Effects of Aging and Hearing Loss

Valeriy Shafiro

Department of Communication Disorders and Sciences, Rush University Medical Center, Chicago, IL, USA

Definition

Environmental sounds comprise a broad and heterogeneous class of acoustic signals which convey meaningful information about objects and events in the listener's surroundings. Environmental sounds are usually distinguished from speech, music, and parametrically generated sounds used in psychoacoustic experiments or clinical tests. Research interest in environmental sound perception in the context of aging and hearing loss is motivated by their importance for individual safety and quality of life as well as their relevance to fundamental questions in perception, cognition, and neurophysiological processing of objects and events in everyday environments. Although environmental sound perception generally remains robust as people age, it is negatively

affected by hearing loss, masking, and complexity of perceptual tasks. Deficits in environmental sound perception may negatively impact listeners' well-being and exacerbate a decline in cognitive abilities and social interactions, potentially leading to further cognitive and neurological deterioration. A better understanding of mechanisms and processes involved in environmental sound perception can inform the development of rehabilitative strategies for older adults with hearing loss, which may also delay age-related cognitive decline.

Detailed Description

Environmental Sound Perception

Environmental sounds are an integral part of most acoustically rich everyday environments, often referred to as auditory scenes (Bregman 1990) or soundscapes (Truax 2001). They provide the listener with information about objects and events in their surroundings. In the course of everyday life, environmental sound perception mostly occurs below the threshold of awareness. However, specific sounds can quickly become the focus of one's attention, alerting listeners to important changes in one's surroundings (Truax 2001; Jenkins 1985). Accurate identification of environmental sounds plays an important role in the listener's safety. Furthermore, environmental sounds can elicit emotional responses (Picou 2016; Husain et al. 2014) and are known to contribute to the overall sense of well-being and connection with one's surroundings (Ramsdell 1978; McRackan et al. 2019; Dixon et al. 2020). Successful environmental sound perception, however, involves two inter-related fundamental problems: (a) parsing complex acoustic signals from auditory scenes into spectral and temporal components which reflect the behavior of multiple distinct sound sources and (b) identifying discrete sound sources with their semantic characteristics and physical properties.

Despite their ubiquity, much less is known about perception and cognition of environmental sounds than about other classes of meaningful sound such as speech and music, or acoustic

stimuli used in psychoacoustic research, which tend to focus on narrowly defined stimulus characteristics. Whereas parametrically generated stimuli used in psychoacoustic research rarely reference specific real world sound sources, environmental sounds tend to convey meaningful information about distal objects and events. Acoustic signals of environmental sounds are acoustic byproducts of mechanical interactions of sound-producing objects (e.g., moving vehicles, tools, animal or human vocalizations, and bodily sounds), or learned arbitrary associations between a particular sound and its meaning (e.g., computer auditory icons, signaling sounds and alarms). In everyday listening environments, individual environmental sounds are typically embedded within auditory scenes, with multiple sequential or simultaneously occurring sound sources. Such arrangements in turn tend to reflect probabilistic contingencies among objects and events that characterize specific environments (e.g., construction sites, intersections, hospitals, schools).

Phylogenetically, environmental sound perception precedes that of speech and music, and differs from these two major sound classes in several important respects. Unlike speech, environmental sounds do not transmit linguistic information following a set of language-specific rules. They are also distinct from traditional music compositions that are primarily structured to convey affective and aesthetic intent. In contrast, when listeners are presented with naturally occurring sounds, they tend to perceive them in terms of underlying sound sources and refer to more abstract auditory qualities only when sound sources cannot be readily identified (Gaver 1993; Ballas 1993; Gregg and Samuel 2009; Marcell et al. 2007; Gygi et al. 2007; Guastavino 2007).

Previous research indicates that healthy adults with normal hearing are able to accurately identify a vast variety of common environmental sounds, often revealing remarkably accurate perception of intricate sound source properties based on sound alone. These include judgments of object size (Carello et al. 1998), and behavior over time, such as anticipating the timing of the next bounce

of a ball after hearing preceding bounces (Gygi et al. 2015). Listeners can similarly identify sex and posture of a walker by the sound of his/her footsteps (Li et al. 1991; Pastore et al. 2008), estimate the fullness of a vessel from the sound of water pouring into it (Cabe and Pittenger 2000), or judge the configuration of two hands from the sounds of clapping (Repp 1987).

In addition to providing instantaneous detailed information about sound sources around the listener, including those outside one's field of vision, environmental sounds can also contribute to non-auditory aspects of perceptual experience and actions. For example, listener's judgments of the crunchiness of potato chips appear to be affected by the chewing sounds, while the enjoyment of a beverage can be affected by the sound of opening its container (Spence and Wang 2015). Environmental sounds also play a role in guiding human actions by providing information about distance and reachability of unseen moving objects through sound alone (Rosenblum et al. 1996; Neuhoﬀ 2004) or through interactions of hearing with other sensory modalities (Ecker and Heller 2005; Castiello et al. 2010; Hauck and Hecht 2019; Roudaia et al. 2013). The walking patterns of healthy adults and Parkinson's patients are affected by the sounds of footsteps they hear (Turchet et al. 2015; Young et al. 2014).

Perceptual organization of environmental sounds appears to be based on the characteristics of their underlying sources or learned arbitrary referents. Multidimensional scaling solutions derived from similarity comparisons of the names of environmental sounds, and separately, from corresponding sounds revealed a similar grouping (Gygi et al. 2007; Lemaitre et al. 2018a). Importantly, the neurophysiological processing of environmental sounds' semantic characteristics appears to be an automatic process, which is engaged even when listeners are not explicitly instructed to attend to environmental sounds' meanings (Orgs et al. 2008).

Existing evidence indicates considerable overlap in the topology of neurophysiological processing involved in the perception of speech and environmental sounds, as well as some degree of dissociation (Dick et al. 2016; Noppeney et al.

2008; Thierry et al. 2003; Humphries et al. 2001; Van Petten and Rheinfielder 1995; Saygin et al. 2010; Tomasino et al. 2015). For instance, activation elicited by hand-manipulated tool sounds differed topographically from activation elicited by animal vocalization (Lewis et al. 2005). The encoding of abstract category properties of sounds of living and human-action sounds appear to be distinct from the neural processing of other non-speech sounds (Giordano et al. 2013). Although some findings support the notion of a dual processing route for the processing of speech and meaningful nonspeech sounds (Thierry et al. 2003; Norman-Haignere et al. 2015), similarities in the neural processing of higher-order conceptual information have also been reported (Schirmer et al. 2011).

Several attempts have been made to construct a comprehensive ecologically based taxonomy of environmental sounds (Gaver 1993; Jenkins 1985) and place environmental sound listening within a larger acoustic communication framework (Truax 2001). To date, however, no single taxonomy has been able to fully capture the complexity of environmental sounds as a class, largely due to their extreme physical heterogeneity and perceptual multidimensionality. Nevertheless, some valuable classifications have emerged. Specifically, a productive distinction has been made between perception of actions and events, on the one hand, and objects and materials, on the other (Warren and Verbrugge 1984; Gaver 1993; Lemaitre and Heller 2012). This basic distinction appears to be supported by both behavioral and neurophysiological findings indicating that perception of actions (e.g., knocking) is more immediate and involves more localized neurophysiological processing, than perception of materials (Lemaitre and Heller 2013; Lemaitre et al. 2018b).

Effects of Aging and Hearing Loss

Aging is a complex systemic process associated with multiple anatomic-physiological, behavioral, psychological, and social changes. In the auditory system, aging affects both peripheral encoding of sensory input and more central information processing (Cardin 2016; Sheft et al. 2015; Humes

et al. 2012; Lin et al. 2011; Bao et al. 2020). One of the better known and extensively documented consequences of aging in the auditory system is presbycusis or age-related hearing loss. Presbycusis is typically associated with a progressive bilateral rise in audibility thresholds, especially in high frequencies, which sometimes precedes more severe sensorineural hearing loss or combines with other types of hearing impairments. In addition to reduced audibility, central effects of presbycusis include deficits in perception of spectral and temporal characteristics of acoustic signals at suprathreshold audibility levels (Humes et al. 2010; Sheft et al. 2012; Füllgrabe et al. 2015).

Changes in sensory processing associated with aging are further accompanied by a decline in auditory-specific and domain-general cognitive abilities involved in higher-level information processing (Lin et al. 2013). However, the rates of decline vary considerably across individuals and also across specific cognitive abilities (Park et al. 2001; Hartshorne and Germine 2015). A subset of cognitive abilities, referred to as fluid intelligence (e.g., working memory, problem-solving), tend to reach performance peak earlier in life and decline sooner than a subset of cognitive abilities, referred to as crystallized intelligence, relating to general world knowledge (e.g., vocabulary size). Although currently specific mechanisms responsible for age-related changes in auditory information processing are not fully understood, a number of contributing factors have been identified (Humes et al. 2010; Pronk et al. 2019; Humes and Young 2016; Pichora-Fuller et al. 2016).

Given the pervasiveness of aging-related changes, a number of effects have been observed for all categories of complex meaningful sounds, including environmental sounds (Aydelott et al. 2010). Generally, identification of isolated everyday familiar sounds presented in quiet appears to be well preserved in healthy older adults with normal hearing or mild hearing losses (Ballas and Barnes 1988; Harris et al. 2017; Shafiro et al. 2020). Differences in environmental sound perception between older and younger listeners become more pronounced when stimulus quality is degraded due to reverberation, signal

processing distortions, or masking by extraneous sounds (Dick et al. 2016; Gygi and Shafiro 2013). Similarly, performance of older listeners is also more negatively affected than that of young adults when task complexity is increased, resulting in a greater cognitive load and leading to more effortful listening (e.g., attending to several sounds or performing more than one task).

When identifying environmental sounds in naturalistic auditory scenes, some of the acoustic cues used to identify individual sounds may become inaccessible due to energetic masking by other sounds in the scene. In addition, semantic characteristics of other sounds in the scene may also influence identification of target sounds (Ballas and Mullins 1991; Leech et al. 2009). The effect of scene context was investigated by Gygi and Shafiro (2013) who asked listeners to identify individual environmental sounds embedded in naturalistic auditory scenes which were either semantically congruent with the target sound or semantically incongruent with it (e.g., a horse galloping at a race track scene vs. in a restaurant scene). An effect of semantic congruence was observed for both younger and older adults. For both listener groups, the direction of the context effect, facilitatory or inhibitory, was mediated by the signal-to-noise (SNR) ratio. At high SNR ratios identification was higher for sounds incongruent with the scene, while the reverse was observed for lower SNRs where greater overall accuracy was observed for sounds which were semantically congruent with the scene. However, younger and older adults differed in overall performance accuracy. Older adults demonstrated significantly lower overall identification accuracy regardless of semantic congruency. This difference in performance appeared to be largely due to reduced audibility of high frequencies, which is typical of presbycusis. When a new group of young adults was presented with the same stimuli lowpass filtered at 4 kHz, the performance of young adults was similar to that of older listeners.

Limitations in the quality and quantity of sensory input in older adults with hearing loss can further exacerbate difficulties in environmental sound perception. Shafiro and colleagues

(2016) presented listeners of different age and hearing status with sequences of five familiar environmental sounds and asked to identify each sound and arrange the sounds in the order they were presented. In half of the sequences, the sounds were semantically coherent (e.g., snoring, rooster, alarm clock, yawn, bird chirping), while in the other half of the sequences individual sounds lacked any apparent semantic coherence. The overall benefit of coherent semantic context was observed regardless of age and hearing status, with no differences in the ability to identify individual sounds which were part of the sequences. Performance differences emerged, however, when correct presentation order was taken into account, possibly because this component of the task requires greater working memory involvement. Young adults outperformed both older normal hearing listeners and listeners with mild-to-moderate hearing loss, with the latter two groups performing at a similar accuracy levels. When the test was given to listeners with cochlear implants (CIs), devices that provide direct electrical stimulation of the auditory nerve bypassing typical peripheral auditory processing, further differences were observed. Although CI listeners' performance on coherent sequences was comparable to that of older normal hearing and hearing impaired groups, they demonstrated particular difficulties with incoherent semantic sequences, suggesting that CI listeners may be even more reliant on contextual cues when identifying environmental sounds.

Indeed, previous research has consistently demonstrated that for CI listeners environmental sound identification accuracy is substantially reduced, even when sounds are presented one at a time in quiet under the ideal listening conditions (Reed and Delhorne 2005; Inverso and Limb 2010; Looi and Arnephy 2010; Shafiro et al. 2011; Lee and Kim 2011). This has been found in children who were implanted early in life (Liu et al. 2013) and also in postlingually implanted adults who have received their implants postlingually, after developing aural language communication abilities (Harris et al. 2017). Recent research further indicates that in postlingually implanted adults, environmental sound

identification, on average, does not appear to exceed that of hearing impaired adults who are cochlear implant candidates, even as the average speech perception accuracy improves following implantation (McMahon et al. 2018; Harris et al. 2019). Possibly, unlike speech perception which can remain robust with primarily envelope cues (Shannon et al. 1995), accurate identification of many environmental sounds relies to a much greater extent on dynamic spectral changes and temporal fine structure of the corresponding acoustic signals. Nevertheless, positive changes in environmental sound identification could still be achieved following training (Shafiro et al. 2015).

Recent findings with a free sorting task in which CI listeners were asked to group a number of sounds based on any criteria they choose, revealed gradual changes in perceptual organization of environmental sounds following implantation (Strelnikov et al. 2018). Whereas the initial post-implantation grouping reflected CI listeners' reliance on sounds' acoustic characteristics, over time, their grouping of sounds began to reflect sounds' semantic categories, suggesting more general reorganization in mapping sounds to their meanings.

Reduced hearing abilities in older adults can also exacerbate existing cognitive deficits. Coebergh et al. (2020) tested environmental sound perception in older adults with mild Alzheimer's disease. Participants with greater agnosia for environmental sounds had higher pure-tone thresholds, even though their average audibility threshold remained within normal limits. Furthermore, mild-to-moderate hearing loss has been shown to be a significant factor in reducing listener ratings of emotional valence of environmental sounds (Picou 2016). This finding corroborated earlier reports of systematic differences in the distribution of brain activity patterns in normal hearing and hearing impaired listeners, following exposure to environmental sounds with varying emotional valence (Husain et al. 2014). It is conceivable that reduction in the range of emotional responses to objects and events in one's surroundings, mediated by hearing loss, can have a negative effect on individual sense wellbeing.

As research interest in environmental sound perception has continuously grown over the last several decades, there is an increased awareness of the practical and theoretical importance of environmental sounds and of the limitations in our current knowledge. While many aspects of environmental sound perception remain robust in older listeners, a number of age and hearing loss related deficits may contribute to increasing psycho-social difficulties encountered by older adults with hearing loss, with implications for individual safety and quality of life (Hamel et al. 2020; Bliss 2000; Dixon et al. 2020). Within the patchwork of subjective experiences of one's daily life, much remains unknown about contributions of environmental sounds to the person's movements and interactions across modalities including touch, taste, vision. A better understanding of the role environmental sounds play in the perception of objects and events in one's surroundings can be instrumental in the advancement of general models of meaningful sound processing. It can also contribute to the development of effective diagnostic tests and rehabilitative strategies for prevention and treatment of hearing loss and age-related cognitive changes.

Enzyme Kinetics, Modeling of

Kim T. Blackwell

Department of Bioengineering, George Mason University, Fairfax, VA, USA

Molecular Neuroscience Department, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

Definition

Mathematical formulation of the rates of chemical reactions that are catalyzed by enzymes, which are molecules that are regenerated as part of the chemical reaction.

Detailed Description

Models of reaction–diffusion systems consist of bimolecular reactions, enzyme reactions, and diffusion. An enzyme is a molecule that facilitates a reaction or transformation of a substrate molecule into a different molecule(s), known as the product. For example, ATP can be transformed into cAMP + PPi spontaneously at an extremely low rate; adenylyl cyclase is an enzyme that greatly facilitates the transformation. The theory behind enzyme reactions is that a large energy barrier prevents a reaction from occurring spontaneously, and the enzyme lowers the energy barrier.

Enzyme reactions are modeled as a series of elementary reactions. First, the enzyme (*E*) and substrate (*S*) bind to each other to form the enzyme-substrate complex (*ES*). Second, the substrate is transformed into the products. Third, the product(s) dissociates from the enzyme:

If two products are created by the enzyme, then they may or may not dissociate in a particular order. For example, during conversion of ATP into cAMP, PPI is more likely to dissociate from adenylyl cyclase after the cAMP (Dessauer and Gilman 1997). In principle enzyme reactions are reversible, though the backward rate is typically extremely low.

Because the rate of catalysis is measured by observing formation of the product, most models of enzyme activity condense the catalytic step and product dissociation into a single, nonreversible step:

In the following treatment, we assume that the mass action approximation is valid. This implies that the number of molecules is great enough to be represented as a continuous valued concentration. Deriving the mathematical equations for an enzyme reaction, or indeed for any system of equations, involves (1) writing an equation for the time-dependent concentration of each molecule in the system and (2) including terms describing rates of production (with a positive sign) and rates of consumption (with a negative sign). These rates are calculated from the concentration of the reactants multiplied by the rate constant. For reaction Scheme 1, this approach produces a system of five ordinary differential equations (ODEs). The simpler system of four ODEs for the system of two enzyme reactions (Scheme 2) is

$$\begin{aligned} \frac{d[S]}{dt} &= -k_f[E] \cdot [S] + k_b[ES] \\ \frac{d[E]}{dt} &= -k_f[E] \cdot [S] + k_b[ES] + k_{cat}[ES] \\ \frac{d[ES]}{dt} &= k_f[E] \cdot [S] - k_b[ES] - k_{cat}[ES] \\ \frac{d[P]}{dt} &= k_{cat}[ES] \end{aligned} \quad (3)$$

where the square brackets $[]$ indicate the concentration of the molecule. Note that though the

catalysis was assumed irreversible, adding in a reverse catalysis term is straightforward. Solving this system of equations requires initial conditions, i.e., the quantity of enzyme, E_0 , and substrate, S_0 . In a closed system, where conservation of mass holds, the system may be simplified using conservation equations. Namely, using $[E(t)] + [ES(t)] = [E_0]$ and $[P(t)] + [S(t)] + [ES(t)] = [S_0]$, the four ODE system can be simplified to a two-ODE system:

$$\begin{aligned} \frac{d[S]}{dt} &= -k_f(E_0 - [ES]) \cdot [S] + k_b[ES] \\ \frac{d[ES]}{dt} &= k_f(E_0 - [ES]) \cdot [S] - k_b[ES] - k_{cat}[ES] \\ [P] &= [S_0] - [ES] - [S] \end{aligned} \quad (4)$$

Under certain conditions, this set of reactions can be simplified still further. The first assumption, which has already been incorporated into the system of ODEs, is that the catalysis step is irreversible. Michaelis and Menten further made the assumption that the substrate, which concentration greatly exceeds the enzyme, is in equilibrium with the ES complex; thus there is no change in the substrate concentration ($dS/dt = 0$). This results in the following equation:

$$\frac{d[P]}{dt} = \frac{k_{cat}[E_0][S]}{[S] + K_D}, \quad \text{where } K_D = \frac{k_b}{k_f} \quad (5)$$

Briggs and Haldane made a slightly different assumption called the quasi-steady-state approximation. They assumed that after initiation of the reaction, the enzyme-substrate complex is in equilibrium: $dES/dt = 0$.

$$\begin{aligned} \frac{d[P]}{dt} &= \frac{k_{cat}[E_0][S]}{[S] + K_M}, \quad \text{where } K_M \\ &= \frac{k_b + k_{cat}}{k_f} \end{aligned} \quad (6)$$

The latter is called the Michaelis-Menten equation. This is generally valid when the initial substrate concentration is much greater than the initial enzyme concentration. Also, the enzyme concentration cannot vary rapidly; else the assumption of

$d[ES]/dt = 0$ is violated. See Chen et al. (2010) for further treatment of the conditions when this is valid.

Especially when modeling signaling pathways, i.e., cascades of bimolecular and enzyme reactions, these assumptions are often violated. Since the product of one reaction is the enzyme for the next reaction, the enzyme concentration is not constant, but varies in time. Also, in some situations substrate is quite small (Ciliberto et al. 2007) or is depleted, as occurs with phospholipase C producing inositol triphosphate from the minor membrane phospholipid phosphoinositol bisphosphate (Brown et al. 2008).

In some cases it is necessary to model the effects of enzyme inhibition. There are several types of inhibition: both reversible and irreversible and both competitive (binding to the same site as the substrate) and allosteric (binding to a different site). With competitive inhibition, the enzyme can function if the substrate concentration is sufficiently high. This can be modeled with an additional reaction, where k_{bi}/k_{fi} is the affinity of the inhibitor for the enzyme (Stenesh 1992):

When modeling enzyme inhibition, this reaction can be included as additional two ODEs to the system of Eq. 3, or under some conditions simplified equations can be written. For example, if the enzyme cannot bind inhibitor and substrate simultaneously, the enzyme inhibitor complex undergoes no further reaction, and the inhibitor concentration is large and remains relatively constant, then an equation similar to the Michaelis-Menten equation results:

$$\begin{aligned} \frac{d[P]}{dt} &= \frac{k_{cat}[E_0][S]}{[S] + K_n \left(1 + \frac{1}{K_I}\right)}, \quad \text{where } K_M \\ &= \frac{k_b + k_{cat}}{k_f}, \quad \text{and } K_I = \frac{k_{bi}}{k_{fi}} \end{aligned} \quad (8)$$

This equation implies that a competitive inhibitor effectively increases K_M (decreases affinity of enzyme for substrate).

Allosteric inhibitors bind at a site different from the substrate-binding site, thus both the inhibitor and the substrate can bind to the enzyme simultaneously. If either S or I can bind first, the following reaction scheme occurs:

The ESI complex can have catalytic activity; however, if it does not, then again with simplifying assumptions a single equation can describe the effect of inhibition on product formation:

$$\frac{d[P]}{dt} = \frac{k_{cat}[E_0][S]}{([S] + K_n) \left(1 + \frac{I}{K_I}\right)} \quad (10)$$

where K_I and K_M are as defined in Eq. 8. This is known as noncompetitive inhibition (Stenesh 1992). If the inhibitor will bind only to the ES complex, then uncompetitive inhibition results:

$$\begin{aligned} \frac{d[P]}{dt} &= \frac{k_{cat}[E_0][S]}{K_n + [S] \left(1 + \frac{I}{K_I}\right)}, \quad \text{where } K_I \\ &= \frac{k_{bi}}{k_{fi}} \end{aligned} \quad (11)$$

All of the above assume that the enzyme requires only a single substrate. In some cases the enzyme may require two (or more) substrates or two molecules of the same species (<http://www.chem.qmul.ac.uk/iubmb/kinetics/ek1t3.html>):

In fact, all phosphorylation reactions require two substrates – the molecule to be phosphorylated and the ATP or GTP donating the phosphate

group. A system of ODEs describing this reaction can be written using the procedure described above. Alternatively, if one of the molecules is rate limiting, e.g., the reaction speed is limited by the concentration and/or binding rate of one of the substrates (known as the rate-limiting substrate), and the other substrate is in excess and/or binds rapidly, then it is often not included in the system of ODEs.

When modeling enzyme reactions involving low numbers of molecules, as occur in small structures such as dendritic spines, then a stochastic approach is often applied. Under these conditions, the assumptions used to simplify the equations often are not valid (Tzafriri and Edelman 2005; MacNamara et al. 2008). Instead of writing equations describing the change in concentration, the reaction master equation is a set of equations describing the probability of change in molecule number:

$$\frac{\partial P(x, t|x_0, t_0)}{\partial t} = \sum_{j=1}^R [a_j(x - v_j) \cdot P(x - v_j, t|x_0, t_0) - a_j(x) \cdot P(x, t|x_0, t_0)] \quad (13)$$

where $\mathbf{x}$ is a vector of molecule quantities and $a_j(\mathbf{x}) dt$ is the propensity of reaction j during the infinitesimal time interval dt (e.g., $a_j(\mathbf{x}) = k_j x_1 dt$ for a unimolecular reaction involving species S_1 and $k_j x_1 x_2 dt$ for a bimolecular reaction involving species S_1 and S_2). The stoichiometry matrix, $\mathbf{v}$, specifies the change in population i when the j th reaction occurs. This formulation includes both enzyme reactions and bimolecular reactions. This equation cannot be solved except for trivial systems, but Monte Carlo techniques are typically applied to generate trajectories (valid solutions).

Definition

Epidural stimulation is the mode of electrical activation of neuronal structures by electrodes implanted in the epidural space. Theoretically, epidural electrodes can be placed anywhere overlying the dural mater of the nervous system, but they typically have been placed over the spinal cord or overlying the cortical region of the brain. Clinical application of epidural stimulation is connected with pain control, treatment of spasticity, and regulation of motor functions after neurological disorders. Another newly developed application of epidural stimulation is to facilitate improved sensory-motor function after paralysis as a result of spinal cord injury. A third application of epidural stimulation that is emerging is its use as a chronically implanted device to be used for a neurophysiological assessment of functional connectivity along specific descending and ascending sensory and motor tracts. This can be particularly useful in assessing the severity and location of neural injuries.

Detailed Description

Analgesic Effect Induced by Epidural Stimulation

Although the mechanisms of analgesic action of epidural stimulation of the spinal cord are unknown, one hypothesis is that selected frequencies and strengths of stimulation can obtain an analgesic effect by releasing neurotransmitters (GABA, glutamate, serotonin), and potentially suppressing the hyperexcitability of spinal neurons (Oakley and Prager 2002). Another hypothesis is that the chronic levels of some stimulation parameters can directly impose an analgesic effect biophysically by changing the electrical conductivity of axonal and dendritic projections of neurons (Guan et al. 2010).

Spinal Structures Activated by Epidural Stimulation

It has been known for several decades that stimulation of the spinal cord with electrodes placed

epidurally over selected spinal segments can be used to stimulate spinal networks. There has been a significant effort and some success in modeling current penetration within the spinal cord. Ideally, we need to know how a given intensity, frequency, pulse waveform of the stimulation, given the physical characteristics of the electrode and the conductivity characteristics of the multiple types of tissues (e.g., skin, subcutaneous fat, bone, the dura mater cerebrospinal fluid, vasculature), generates a given effect on specific *neural* structures. Based on computer modeling data it has been suggested that the order of excitation of spinal elements during epidural stimulation applied to posterior surface of the spinal cord is the following. First, the large myelinated fibers entering through the dorsal roots will be activated, then myelinated fibers of dorsal columns (Coburn 1985; Holsheimer 2002, Finite Element Modeling for Extracellular Stimulation elsewhere in this Encyclopedia).

Pain Control by Epidural Stimulation

The most experience with epidural stimulation of the spinal cord, by far, has been its use in efforts to suppress chronic pain (Shealy et al. 1967; Barolat 2000). The mechanism for pain suppression remains poorly understood except to say that it generates some level of anesthesia of the underlying neural structures and perhaps to areas where these neural structures may project. According to the gate theory the electrical spinal cord stimulation activating the large afferent fibers in dorsal roots close the “gate” eliminating painful inputs to the spinal cord (Melzack and Wall 1965).

Thousands of stimulators and electrode arrays are chronically implanted annually in subjects with spinal cord injury as well as for other pain disorders. As a medical intervention strategy for treating pain these implants have proven to have varying degrees of success, some being extremely successful others being ineffective. In terms of safety and durability these chronic implant procedures have been proven to be relatively routine, safe and functional for years.

Neuromodulation of Locomotor Behavior by Epidural Stimulation

Epidural electrodes placed on the spinal cord was proven to be effective in inducing locomotion in decerebrated animals more than two decades ago (Iwahara et al. 1991). In this preparation bipolar electrodes can be placed over cervical or lumbar segments to induce locomotor-like movements. More recently these epidural electrodes have also been used to neuromodulate the physiological state of different networks along the length of the spinal cord in a manner that enables rather than directly induces animals with complete paralysis to regain the ability to step in highly coordinated fashions (Gerasimenko et al. 2008). Following a complete transection of the spinal cord at the mid-thoracic level, with motor subthreshold or near threshold levels of epidural stimulation, the hind limbs of the rat can step forwards backwards or sideways and readily adjust to the speed of the treadmill belt (Courtine et al. 2009). To accomplish this, in essence, the epidural stimulation neuromodulates the properties of the spinal circuitry so that the spinal circuitry can interpret and subsequently execute the motor patterns necessary to accommodate the external mechanical conditions which is continuously monitored by a range of proprioceptors and cutaneous fibers. Again, which neural structures and how the specific structures are being neuromodulated at the cellular and network level are poorly understood. It is highly significant, however, that not only can this epidurally mediated neuromodulation facilitate standing and stepping in laboratory animals, but this same approach is proving to be highly successful in humans even with complete paralysis to regain independent standing and even some voluntary control of the lower limbs (Harkema et al. 2011).

This epidurally mediated neuromodulation is now being tested for a variety of other functions. For example, there is reason to think that neuromodulatory techniques as used to facilitate posture and locomotion could also be effective in modulation of the cervical spinal cord to improve upper limb function. Neuromodulatory interventions using epidural electrodes can be used also in conjunction with motor training to enhance rehabilitative procedures. Another valuable use of

epidurally implanted electrodes that is proving to be significant is its application as a neurophysiological tool for assessing in vivo the ability of the spinal circuitry to process the cutaneous and proprioceptive input to the spinal cord while the subject is performing a specific motor task (Shah et al. 2012).

Another application of chronically implanted epidural electrodes has been demonstrated by placing electrode arrays over the motor cortex. These type of implants can be used as an in vivo assessment tool for testing descending as well as ascending sensory-motor pathways when the subject is actually performing a motor task (Suner et al. 2005). And given the evidence that activity can be used to modulate the development of new neural supraspinal connections following a spinal or brain stem injury to the motor system, it has the potential for serving as a facilitator of enhancing supraspinal-spinal interconnections over a period of weeks.

Definition

Epilepsy is a set of neurological disorders and syndromes characterized by recurrent seizures. Neural Population Models can serve as

biomathematical representation of an abnormal neuronal assembly by altering parameters to reproduce epileptiform activity. Typically, parameters related to excitatory or inhibitory synaptic transmission can be modified (with respect to physiological values) to generate events that match those actually observed in local field potentials or in the EEG during ictal (seizures) or interictal (outside seizures) periods.

Detailed Description

Epilepsy is a pathological condition in which the nature of the interactions between neurons and the properties of neurons themselves are altered. These alterations lead to the development of epileptogenic networks in the brain over which transitions from normal to epileptic activity can spontaneously occur. Epileptogenic networks consists in extended networks of neurons characterized by abnormal synchronization properties (as revealed by synchrony measures performed on intra- and/or extra-cellular signals) (Jiruska et al. 2013) and by hyperexcitability (as revealed by excessive firing) (Babb et al. 1984).

Neural population models (NPMs) have intrinsic properties that are particularly suited in the context of epilepsy. First, and conversely to detailed approaches, NPMs are not based on the explicit representation of each single neuron. They assume that neurons in a given brain area are organized as a population, itself composed of interconnected sub-populations (for instance, pyramidal cells and interneurons in the cortex). Ensemble dynamics are rising from average synaptic interactions between interconnected sub-populations. Therefore, within a sub-population high synchronization between neurons is implicitly assumed. This high synchronization, also referred to as hyper-synchronization, is often encountered during epileptic activity. Second, excitability conditions can be easily modified in NPMs (through the average amplitude of post-synaptic potentials or through the average number of synaptic contacts between sub-populations) allowing for the simulation of hyperexcitable systems. Finally, individual NPMs can be easily coupled (Wendling et al. 2000) to form for

large-scale epileptic systems as those encountered in partial epilepsies (see for instance (Bartolomei et al. 2001) for temporal lobe seizures) or in generalized epilepsies (see for instance (Robinson et al. 2002) for absence seizures).

NPMs in Partial and Generalized Epilepsies

The two sections that follow are intended to provide examples of insights gained from NPMs in the context of partial and generalized epilepsies. Readers may refer to (Suffczynski et al. 2006b; Lytton 2008; Soltesz and Staley 2008) for more detailed description of neuronal population models as used in the context of epilepsy.

In partial epilepsies, these models were also used to investigate the interictal to ictal transition. Wendling and co-workers showed how a generic neuronal population model can be modified (i) to better approach the specific cytoarchitecture of brain structures like the hippocampus (Wendling et al. 2002), the enthorhinal cortex (Labyt et al. 2006) or the neocortex (Molae-Ardekani et al. 2010) and (ii) to reproduce electrophysiological patterns recorded in these structures during the transition to seizure.

An example is provided in Fig. 1 in the context of mesial temporal lobe epilepsy (MTLE). As illustrated (Fig. 1a), the transition from interictal to ictal activity is characterized by first the emergence of sporadic spikes (a), and then by a rhythmic spiking activity (b) followed by a fast activity (c) which is generally considered as the onset of

Epilepsy, Neural Population Models of, Fig. 1 Epilepsy, Neural Population Models of (a) Depth-EEG signal recorded from hippocampus in a patient with temporal lobe epilepsy (TLE) during the interictal to ictal transition. (b) LFP simulated with the neuronal population model described in (Wendling et al. 2005) when one inhibition-related parameter is gradually decreased as a function of time. Lower case letters indicate the type of

dynamics observed in LFPs: sporadic spikes (a), rhythmic spikes (b), fast activity (c), and, ictal activity (d). (c, d) Time-frequency representations (spectrograms) focusing on the typical fast activity occurring at the onset of the seizure. In both real and simulated signals, a narrow band signal (arrow) in the low gamma frequency band is generated (See text for details)

the seizure. This fast onset activity is typically in the beta or low gamma EEG frequency band (15–40 Hz) and gradually slows down in the frequency domain. It usually indicates a transition to an ictal narrowband highly-rhythmic high-amplitude activity (mostly within the EEG theta band, 5–10 Hz) (d). This typical electrophysiological pattern was investigated using NPMs (Wendling et al. 2005). As illustrated (Fig. 1b), the gradual decrease of the synaptic gain in the inhibitory loop leads the NPM to generate a typical sequence of activities reflected in real depth-EEG signal during the transition to seizure: normal background activity, sporadic spikes (a), rhythmic spikes (b), fast activity (c), ictal activity (d). The visual inspection of simulated signals shows that real waves are quite accurately reproduced by the model. Overall, insights were gained about excitability changes during transition to seizures MTL: the conjunction of increased excitation with gradual disinhibition leads to ictal activity in the proposed NPM of the hippocampal circuit. In addition, as this NPM includes two subsets of inhibitory interneurons (targeting dendritic and somatic receptors of pyramidal cells), observed dynamics and transitions could be explained. In particular, the fast seizure onset activity could be related to the fast feedback inhibitory loop present in the NPM. Experimental validation was brought afterwards (Gnatkovsky et al. 2008).

In the context of generalized epilepsies, NPM-based representations of the thalamo-cortical system were also proposed (Suffczynski et al. 2001, 2006a; Breakspear et al. 2006; Roberts and Robinson 2008). Models were designed accounting for interactions between neocortical and thalamic circuits. Mechanisms of transition between background EEG activity and rhythmic spike-wave discharges were investigated (Marten et al. 2009) and model predictions were compared with results obtained in different experimental models of absence epilepsy or in human (Crunelli et al. 2011). In particular, Lopes da Silva and co-workers obtained mechanistic insights regarding the generation of spike and wave discharges (SWs), as observed in absence seizures (Suffczynski et al. 2004). These results were

obtained through model simulations and system analysis. Authors found that SWs appear and stop spontaneously without any change of model parameters. Bifurcation analysis showed that the thalamo-cortical network exhibits bistable dynamics and attractor changes depend on the noise present in the network. As the distributions of ictal and seizure free epoch durations are exponential, authors concluded that transitions between the two stable states (background, ictal) occur randomly over time. This model prediction was validated using experimental data from animal models of absence epilepsy. Finally, as the sudden onset of large paroxysmal activity is triggered by a stochastic process, the occurrence of this type of seizures is unpredictable per definition.

Definition

A major unit in computational multi-scale modeling in epilepsy is the ion channel. Ion channels can be represented in silico by discrete mathematical formulas describing their biophysical properties while detecting and responding to a stimulus. The stimulus causes the channel protein to undergo a series of three-dimensional conformation changes which opens or closes the channel which regulates ion flow through the transmembrane pore formed by alpha-helix polypeptide subunits.

Detailed Description

Ion Channel Function

Fundamentally, an ion channel acts as an energetically favorable pathway for small charged molecules (ions) to pass through the cell membrane (Hille 1984). Ion channels are integral transmembrane proteins that exist as oligogenic macromolecular complexes including a pore-forming alpha subunit and modulatory and accessory subunits (Sharman et al. 2013; Alexander et al. 2011). Functionally, an ion channel responds to a stimulus, which may be mechanical (e.g., stretch), chemical (e.g., a neurotransmitter), or electrical (e.g., change in transmembrane voltage). This causes the channel to open a selectively permeable low-resistance path

for charged ionic species, either anionic (chloride (Cl^-)) or cationic (calcium (Ca^{2+}), potassium (K^+), sodium (Na^+)), or both (e.g., Ih). The ions pass from one side of the lipid bilayer to the other, down their electrochemical gradient (Hille 1984).

Gene mutations which encode missense amino acid substitutions, or produce premature stop codons resulting in truncated (shortened) proteins, impact static and dynamic ion channel function (Lerche et al. 2013; Lehmann-Horn and Jurkat-Rott 1999). Such changes may be associated with either inherited or sporadic epilepsy. In the latter case, although the channel variant is inherited, it is only part of a confluence of multiple factors that produce the acquired pathology. Changes in the biophysical properties of ion channel function can be used to investigate and/or define structure/function relationships in ion channel proteins using homology models and/or used to populate and assess function of computer models of neuron and network models (Capener et al. 2002; Case et al. 2012).

Epilepsy as an Excitability Disorder

Epilepsy is an excitability disorder characterized by abnormal synchronization of populations of cortical neurons. An excess of excitation and/or a change in neuronal network inhibition can lead to the electrographic hyperexcitability defect (England et al. 2012a, b). Ion channel gene mutations in both mouse and man have been shown to cause both inherited and sporadic forms of epilepsy through disrupted ion channel function (Noebels 1999; Reid et al. 2009; Mulley et al. 2003). Computational models of ion channel mutations in epilepsy have functional consequences which can be simulated by looking at homology models of three-dimensional protein structure. One can also predict aberrant cellular and/or network behavior based on the biophysical parameters of the mutant ion channel protein, and on its interactions with other ion channels.

Homology Models of Mutant Ion Channels

Homology models of ion channel proteins allow determination of the tertiary protein structure resulting from an amino acid substitution encoded by a non-synonymous genetic variant (a synonymous mutation leaves the amino acid unchanged) (Ravna and Sylte 2012). These models are particularly useful because ion channel proteins, massive macromolecular complexes that span the lipid membrane, are not amenable to standard crystallographic techniques (Capener et al. 2002). In a homology model, amino acid sequence similarity to proteins of known structure is combined with free-energy minimization calculations to optimize the energetics of polypeptide packing (Minor Jr 2007). These refined structural models offer an informed *in silico* approximation of tertiary protein-protein interactions of ion channel domains. Models of ion channels harboring missense mutations frequently focus on regions of high conservation (e.g., voltage sensor motif, ion selectivity filter) where physiochemically related protein structures can be used to predict disruption of polypeptide secondary structure (e.g., salt bridge neutralization, proline kink in transmembrane alpha-helix) as an indicator of pathogenic consequence (e.g., using PolyPhen or SIFT software, which are polymorphism phenotyping prediction tools) (Adzhubei et al. 2013; Flanagan et al. 2010).

Epilepsy Mutation Causing Dysfunction of Ion Channels in Neuronal and Network Models

Hyperexcitable epilepsy-related cell and network models have been developed which integrate genetic, biological, and pharmacological data. Ion channels are integral components of many of these models because of multiple feedback mechanisms: they both regulate and respond to the changes in transmembrane voltage. Ion channels are readily described by mathematical formulas which describe their biophysical responses (e.g., kinetics of channel opening) during dynamic

changes in membrane potential and the regulation of ion passage through the channel pore. When the biophysical parameters for epilepsy mutation containing ion channels (e.g., Nav1.1) are used to populate *in silico* models, changes in cellular signaling (e.g., action potential duration, spike frequency) can be observed. These predictions can then be tested by comparison with *in vivo* and *in vitro* data (Thomas et al. 2009; Mulley et al. 2005).

²Department of Pediatrics, The University of Chicago, Chicago, IL, USA

Detailed Description

Epilepsy is a serious neurological disorder characterized by spontaneous recurrent seizures. In the electroencephalogram (EEG) of patients with epilepsy, one may observe seizures (ictal

events) and interictal events, e.g., epileptic spikes or spike-waves. These events are characterized by a short duration and rapid onset and offset. The real problem is that about 30% of the current population of 60 million patients with epilepsy does not respond to any treatment (Kwan and Brodie 2000). This problem is mostly due to an incomplete understanding of the mechanisms that underlie this pathology (e.g., van Drongelen 2007). As is the case for many other neurological diseases, this directly relates to a poor understanding of network function in general. Because of lack of experimental tools for studying network behavior at sufficient scale with the associated detail (e.g., van Drongelen 2010a,b), there is a significant role for modeling in this field (e.g., Blenkinsop et al. 2012; Cosandier-Rim    et al. 2010; Goodfellow et al. 2012; Lytton et al. 1997; Lytton and Sejnowski 1991; Lopes da Silva 2008; Lytton 2008; Soltesz and Staley 2008; Touboul et al. 2011; Traub and Llinas 1979; Traub et al. 1994; van Drongelen et al. 2004, 2005, 2006, 2007, 2008; Wendling and Chauvel 2008; Wendling et al. 2012).

Why Modeling in Epilepsy/Neuroscience?

Understanding the function of neuronal networks is a frontier in current neuroscience. Our lack of fundamental understanding of network function in the nervous system prevents us from linking neuronal activity to higher level physiologic and pathologic behavior. Although compound activity of huge networks can be captured by the EEG or possibly by functional magnetic resonance imaging (fMRI), current experimental techniques in neuroscience cannot record the individual activity of cells forming larger networks (>1,000 neurons) with sufficient resolution in the time domain (<1 ms). Due to the lack of such techniques, there is a real need for theoretical and computational models in neuroscience because they can provide a framework for the integration of experimental data. In addition, models provide an efficient tool for generating and testing series of hypotheses; to cite Abbott (2008), "A skillful theoretician can formulate, explore, and often

reject models at a pace that no experimental program can match."

Modeling of Neuronal Network Activity

Node-Based Models When modeling neuronal networks, one can start from the network nodes, i.e., the neurons, or make direct assumptions at a higher organization level, i.e., the population activity. In the first case, the bottom-up approach, one must decide how to model the nodes. Simple on/off switches are the most abstract models of neurons in networks. The underlying hypothesis of this approach is that, for some of the aggregate behavior, the network properties themselves are of principal interest while the details of the cellular properties (beyond having active and inactive states) are irrelevant (McCulloch and Pitts 1943; Little 1974; Hopfield 1982; Benayoun et al. 2010; Wallace et al. 2011). Many network models that use the bottom-up approach include more complex representations for the nerve cells and their connections. These representations may vary from a simple IF model to compartmental models including biophysically realistic channels (e.g., van Vreeswijk et al. 1994; van Vreeswijk 1996; Olmi et al. 2010; Tattini et al. 2012; Izhikevich and Edelman 2008; Traub and Miles 1991; Traub et al. 2005; Lytton and Sejnowski 1991; De Schutter and Bower 1994; van Drongelen et al. 2005, 2006, 2007; Markram 2006).

Population-Based Models A different family of network models describes aggregate behavior of neuronal populations. Although the components of these models are derived from or inspired by the neuronal function, they do not explicitly consist of a network of individual agents. This approach was pioneered by Wilson and Cowan (1972, 1973). Their result is a nonlinear, two-dimensional model describing the dynamics of excitatory and inhibitory activity. The expressions for the population activity are based on assumptions about cellular statistics such as the distribution of neuronal excitability. The initial 1972 Wilson-Cowan model describes only the

time-dependent dynamics of the neural populations, whereas their 1973 paper includes a spatial component to this model. In the same decade, Nunez proposed models of cortical networks to explain and describe the electroencephalogram (EEG) representing compound activity of millions of nerve cells (Nunez 1974, 1995; Nunez and Srinivasan 2006a, b). This work focused on the synaptic activities in the cortical pyramidal cell population since they are considered to be the major contributors to the mammalian EEG. To describe cortical activity, Nunez included inhibitory and excitatory populations and used linearized relationships to describe their interactions. Since the early 1970s, many models have been inspired by the Wilson–Cowan approach and the models by Nunez. Examples are the models by Lopes da Silva et al. (1974) and van Rotterdam et al. (1982), the Jansen neural mass model (Jansen and Rit 1995; Grimbert and Faugeras 2006), and Freeman’s models of the olfactory system (Freeman 1987; Chang et al. 1998). More recent examples are the models by Wendling and co-workers (e.g., Wendling and Chauvel 2008), Liley and Bojak (2005), van Albada and Robinson (2009), and Hindriks and van Putten (2012). A model developed by Jirsa and Haken (1997) produces a field equation for the network activity generated by a cortical surface and can be considered a synthesis of the different population model approaches. In part due to increased access to computer technology facilitating the analysis of nonlinear dynamics, the original Wilson–Cowan approach and its derived models are being “rediscovered” (Destexhe and Sejnowski 2009).

The Wilson–Cowan Model The first model by Wilson and Cowan (1972) is exclusively temporal and describes the behavior of two neuronal populations – one excitatory and one inhibitory – embedded in neural tissue. In the Wilson–Cowan model, population properties are derived from assumed statistics of the neurons (Wilson and Cowan 1972). Each population receives input from itself, the other population, and external

sources. The input to a population affects the neurons of that population that are available (the inactive proportion of the population). The model is nonlinear as the level of excitation is related to the output activity through a sigmoidal function S . In a 2nd version of the model that will not be further discussed here, Wilson and Cowan (1973) extended their model to include the spatial component as well. Instead of formulating the model from underlying statistical properties, a coarse-grained version of the model can be directly derived from the diagram in Fig. 9. Two populations, the excitatory and inhibitory, are coupled with strengths c_1 – c_4 . The external population affects the excitatory and inhibitory networks with strengths P and Q . Denoting excitatory activity by E and inhibitory activity by I , the excitatory population in Fig. 1 receives input that can be quantified as $c_1E - c_2I + P$. This input of the population is converted to an output expression via the sigmoid function $S_e\{\dots\}$. In most followers of their approach, such a sigmoid curve is employed to represent conversion from membrane potential to spike rate and/or vice versa. In the Wilson–Cowan approach, the sigmoid curve represents the cumulative distribution

Epilepsy: Computational Models, Fig. 1 Diagram of the Wilson–Cowan model containing excitatory and inhibitory populations. The coupling strength between the populations is denoted with constants c_1 – c_4 , and external activity is symbolized by P and Q . Note that the model contains nonlinear functions to relate input and output for each population (not shown in the diagram) (From van Drongelen (2013))

of the probability that a neuron will fire at a given input, i.e., the distance between membrane potential and firing threshold. Further, assuming that the unavailable part of the population, i.e., the active + refractory portion, is proportional (by a fraction r_e) to the activity level E , then the receptive population (available portion of E) is $1 - r_e E$.

The formalism for population activity also must describe spontaneous decay proportional to E , reflecting that a non-stimulated group of neurons converge to a base level of activity (zero, reflecting a low level of spontaneous activity in this model). Finally, all changes dE/dt are weighted by the time constant of the neuronal population τ_e . Putting this all together, the expression for excitatory activity becomes

$$\underbrace{\tau_e}_{\text{Excitatory time constant}} \frac{dE}{dt} = - \underbrace{E}_{\text{Decay}} + \underbrace{(1 - r_e E)}_{\text{Available population}} \underbrace{\text{Sigmoid}}_{\text{Sigmoid}} \underbrace{\{c_1 E - c_2 I + P\}}_{\text{Input}} \quad (1)$$

A similar approach for the inhibitory population yields

$$\tau_i \frac{dI}{dt} = -I + (1 - r_i I) \text{Sigmoid}\{c_3 E - c_4 I + Q\} \quad (2)$$

Considering that this model is two dimensional and nonlinear, it is capable of exhibiting a variety of behaviors including a steady activity scenario, oscillatory activity with damping, and limit cycles.

A detailed bifurcation analysis of the Wilson–Cowan network is given in Borisjuk and Kirilov (1992). In this entry the bifurcation curves of the type Andronov–Hopf, saddle separatrix, and double limit cycle are computed in the parameter plane with P and c_3 as parameters.

Neural Mass Models Inspired by the Wilson–Cowan Approach The model described by Lopes da Silva et al. (1974) is a model of thalamus and one of the first that is inspired by the Wilson–Cowan approach. A similar treatment of the mesoscopic model, with altered synaptic function, was given by van Rotterdam et al. (1982). The base model describes a thalamic network. However, the populations are identical to the ones in the cortical Wilson–Cowan model: one excitatory and one inhibitory cell group.

The Wilson–Cowan equations (Wilson and Cowan 1972) and Lopes da Silva et al.’s approach (Lopes da Silva et al. 1974) inspired many other models. Instead of considering individual neurons, these models determine the activity of coupled populations of nerve cells, each population representing a neural mass. A very basic model, using two populations representing a coupled excitatory and inhibitory network, is described by Dayan and Abbott (2001, pp. 265–270). The rate of change for each network is negative proportional to its activity level and proportional to the input it receives from itself, the other population, and an external input. This results in a set of two coupled differential equations that describe the activities v_E and v_I of the excitatory and inhibitory populations E and I :

$$\tau_E \frac{dv_E}{dt} = -v_E + \{M_{EE}v_{EE} - M_{EI}v_I + \gamma_E\} \quad (3)$$

$$\tau_I \frac{dv_I}{dt} = -v_I + \{-M_{II}v_I - M_{IE}v_E - \gamma_I\} \quad (4)$$

M_{XX} are the coupling strengths between the populations, τ_X denote the time constants, and γ_X represent external inputs (X denotes the E or I population). Although the model seems to be linear, their model is actually nonlinear because $v_E \geq 0$ and $v_I \geq 0$. Therefore, their model is capable of generating limit cycles.

Jansen’s neural mass model (Jansen and Rit 1995) is applied by Grimbert and Faugeras (2006) to create a cortical network unit (Fig. 2a).

It is a temporal model of neuronal populations inspired by the Lopes da Silva et al. (1974) approach where each population is represented by a Wiener cascade (van Drongelen 2010a,b, Chaps. 2–5): a dynamic linear component, modeling the synaptic conversion process, and a non-linear static component that represents the conversion of membrane potential to spike rate (Fig. 2b). As it can be seen in Fig. 2b, input x_1 (input spike rate) is first convolved with the unit impulse response (UIR) h of the linear dynamic component, the result $x_2 = x_1 \otimes h$ (population membrane potential; $\otimes$ -convolution) is subsequently converted with a static sigmoid to produce output $x_3 = \sigma(x_2)$ (output spike rate). The structure of the model by Grimbert and Faugeras (2006) is similar to the canonical cortical model of Douglas and Martin (1991) in the sense that it also includes two excitatory populations E , one inhibitory population I , and an external input P . The development of the equations that govern the activities is straightforward. First, we use the UIR to write a convolution expression. Again, the synapse is considered a linear system, and in this model, the synaptic impulse response function is defined as an alpha function (as in van Rotterdam et al. 1982):

$$h(t) = \begin{cases} \alpha \beta t e^{-\beta t} & t \geq 0 \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

in which α and β are population-specific constants.

The authors employ a static nonlinearity for the membrane potential to pulse rate conversion, a sigmoid curve $\sigma(v)$ (Fig. 2b). In this study it is defined as a Boltzmann function with maximum rate $v_{\max}$, slope r , and a 50% level threshold v_0 : $\sigma(v) = \frac{v_{\max}}{1 + e^{-(v-v_0)}}$. This completes the formalism for one population, i.e., a single Wiener cascade in Fig. 2b. The pair of ODEs plus the static nonlinearity can be defined for each of the three populations in the neural mass model (two excitatory and one inhibitory, Fig. 2a). This means we will have a pair of 1st-order differential

Epilepsy: Computational Models, Fig. 2 Neural mass models. (a) A diagram of the model of a cortical unit employed by Grimbert and Faugeras (2006) and a sample trace showing an oscillation similar to an EEG alpha rhythm. Panel (A1) shows and inhibitory how excitatory networks are connected. Details of the model are shown in (A2); h_e and h_i are the synaptic unit impulse responses; the σ modules are the sigmoid functions translating membrane potential into firing rate; C 's are coupling constants; y 's are defined in Eq. 6. (b) Representation of a Wiener cascade used to model a population of nerve cells. The Wiener cascade consists of a linear dynamical module and a static nonlinear one. (c) Schematic representation of the model described by Freeman (1987) and sample traces showing chaotic behavior of the impulse responses (impulse input – arrows) (Modified from van Drongelen (2013))

equations per population, generating a total of six equations (Eq. 3 in Grimbert and Faugeras 2006):

$$\begin{aligned} \dot{y}_0(t) &= y_3(t) & \dot{y}_3(t) &= Aa & \sigma(y_1(t) - y_2(t)) - 2a & y_3(t) - a^2 y_0(t) \\ \dot{y}_1(t) &= y_4(t) & \dot{y}_4(t) &= Aa & \{p(t) + C_2 \sigma(C_1 y_0)\} - 2a & y_4(t) - a^2 y_1(t) \\ \dot{y}_2(t) &= y_5(t) & \dot{y}_5(t) &= BbC_4 & \sigma(C_3 y_0) - 2b & y_5(t) - b^2 y_2(t) \end{aligned} \quad (6)$$

In Eq. 6, the function $p(t)$ can be taken constant, i.e., $p(t) = p$, whereupon bifurcation analysis can be performed. This is done in [37]. It turns out that a low and a high steady state can stably coexist. On the upper branch there are two values at which a Hopf bifurcation occurs. The first one produces through a subcritical Hopf bifurcation for increasing values of p an unstable branch of periodic orbits that regains stability through a saddle node of cycles and disappears in a homoclinic orbit. This yields a narrow band of p -values for which stable, large amplitude, low-frequency (1–5 Hz) periodic orbits exist. The second Hopf bifurcation point is supercritical, yielding a stable small amplitude periodic orbit with frequency in the alpha range. This orbit disappears again in a supercritical Hopf bifurcation at a higher value of p (see Figs. 4 and 5 in Grimbert and Faugeras (2006)); for convenience, the latter is replicated here (Fig. 3).

The parameters $y_0 - y_2$ denote the membrane potentials, and A, a, B, b are the constants in the population-specific alpha functions. Note that in these equations, some outputs y and sigmoid functions are weighted by connectivity strengths $C_1 - C_4$. The focus of this entry is on the variable y , the aggregate membrane potential of the main population, which is thought to be proportional with the local field potential. A simulation using the following parameters $A = 3.25$, $a = 100$, $B = 22$, $b = 50$, $C_1 = 135$, $C_2 = 0.8 * C_1$, $C_3 = 0.25 * C_1$, $C_4 = 0.25 * C_1$, $v_{\max} = 5$, $r = 0.56$, and $v_0 = 6$ shows a signal that is similar to the EEG alpha rhythm (Fig. 2a).

Network Models with Conduction Delays The models created by Freeman in the 1980s used a combined network modeling and experimental approach to study the electrical activity in rabbit olfactory system. Although Freeman's approach may not have been directly inspired by the Wilson–Cowan equations and/or the models by Lopes da Silva and co-workers, the fundamental building blocks of his model are neural masses. The appeal of Freeman's approach is that it is strongly based on the anatomy of the olfactory system and that he relates modeling results to electrophysiological experiments. As compared to the previous models, a unique addition is that it contains latencies L1–L4, modeling the conduction delays occurring in-between populations (Freeman 1987). Ordinary differential equations

Epilepsy: Computational Models, Fig. 3 Diagram of the stable fixed points and limit cycles in the model by Grimbert and Faugeras (2006). Copy of Fig. 5 in the original paper. Stars indicate the start of two simulated trajectories

Epilepsy: Computational Models, Fig. 4 Bistability near a double Hopf bifurcation in a scalar neural field equation. The patterns show the asymptotic behavior for

different initial conditions. For the parameter settings, see van Gils et al. (2013)

need initial values, whereas delay differential equations require initial functions to determine the solution in future time. This makes it to an infinite dimensional system, even if it is a scalar equation. There is a well-developed theory for delay equations. Local bifurcation theory, for instance, is available after a center manifold reduction. It is a given that delays in the nervous system occur because of the finite conduction velocity of nerve fiber activity. In addition to Freeman's model, several others have explored the role of these delays or included the delays in the formalism (e.g., Foss et al. 1996; Milton 2000, 2012; Visser et al. 2010, 2012).

In his models, Freeman describes different population levels. The most basic population type is defined as $K0$: a subset of noninteracting neurons, either all excitatory ($K0_e$) or inhibitory ($K0_i$). Coupled $K0$ networks create the KI level. In Freeman's terminology, two $K0_e$ modules give a KI_e module, and a pair of $K0_i$ gives one KI_i (Fig. 2c). The next level is the KII

population, i.e., coupled KI_e and KI_i units. The distance between KII populations can be large enough that conduction delays cannot be neglected. These delays are indicated by L in Fig. 2c. Finally, when KII sets are interconnected, a $KIII$ set is created. In Freeman (1987), there are three coupled KII sets: the olfactory bulb, the anterior olfactory nucleus, and the prepyriform cortex. The connections in this set are longer in range so that lags (latencies) were incorporated.

Neural Fields and Effects of Delays

Due to intrinsic delays of axons, synapses, and dendrites in the natural system, the role of delays in spatiotemporal dynamics of neural activity has received considerable attention (Liley et al. 2002; Hutt et al. 2003; Hutt and Atay 2005; Roxin et al. 2005; Venkov et al. 2007; Hutt and Atay 2007; Hutt 2008; Coombes et al. 2007; Coombes and Laing 2009; Coombes 2010).

Epilepsy: Computational Models, Fig. 5 Can seizure onset be modeled with a Hopf bifurcation? (a) A partial complex seizure spreads and grows in amplitude, suggesting one might model it with a supercritical Hopf bifurcation. (b) A generalized seizure occurs suddenly and at full amplitude, similar to a supercritical Hopf bifurcation. (c) Note that the same seizure as in panel (b) can also be explained by a perturbation in a bistable regime associated with the subcritical Hopf bifurcation. In this case the transition into the seizure state is not a bifurcation but due to a change of basin of attraction (e.g., Milton and Jung 2003) (From van Drongelen (2013))

With $p \geq 1$ populations consisting of neurons that occupy fixed positions in a nonempty, bounded, connected, open region $D \subset \mathbb{R}^n$. For each $i = 1 \dots p$ let $V_i(t, r)$ be the membrane potential at time t , averaged over those neurons in the i th population positioned at $r \in D$. These potentials are assumed to evolve in the absence of time-dependent external stimuli according to the system of integrodifferential equations.

$$\frac{\partial V_i}{\partial t}(t, r) = -\alpha_i V_i(t, r) + \sum_{j=1}^p \int_D J_{ij}(r, r') S_j(V_j(t - \tau_{ij}(r, r'), r')) dr' \quad (7)$$

for $i = 1, \dots, p$. The intrinsic dynamics exhibit exponential decay with $\alpha_i > 0$ for $i = 1, \dots, p$.

The propagation delays $\tau_{ij}(r, r')$ measure the time it takes for a signal sent by a type- j neuron located at position r' to reach a type- i neuron located at position r . The functions S_j translate the mean membrane voltage of the j th population into a firing rate. The connectivity functions $J_{ij}(r, r')$ describe how type- j neurons at position r' are connected to type- i neurons at position r . Spectral and stability properties of stationary solutions using methods from functional analysis were obtained in (Veltz and Faugeras 2010; Faye and Faugeras 2010; Veltz and Faugeras 2011). In van Gils et al. (2013), equations of this type are described as abstract delay differential equations. The theory for dual semigroups makes it possible to apply the center manifold reduction and to compute local bifurcations (e.g., Fig. 4).

Application to Epilepsy

Although there are many clinical types of seizure (Berg et al. 2010), the seizure activity in the EEG is often characterized by rhythmic activity usually lasting for minutes. Examples of typical seizure onset activity are depicted in Fig. 5. In contrast, interictal spikes and waves are sudden, short bursts of electrical activity. Although there are exceptions, in between the epileptiform events (i.e., seizures, spikes, waves), the EEG of patients with epilepsy cannot be distinguished from normal EEG patterns. Because epilepsy is characterized by its EEG patterns representing large networks, it is impossible to define epileptiform activity at the level of single neurons or even small networks. Although there seem to be cellular activity patterns frequently found in epileptic brain tissue, such as the paroxysmal depolarization shift (PDS), it is by no means clear how these PDSs relate to the typical network phenomena in epilepsy. The oscillatory activity of cells and small networks is of general interest to the neuroscientist but equally of interest in epilepsy research. However, at this level the distinction between normal and pathologic oscillatory activity is unclear. At the scale of large networks, as reflected in the EEG signal, the distinction between normal and abnormal is not without

problems but definitely easier to make. This makes the study of networks at mesoscopic and macroscopic scales of particular interest in epilepsy research. Based on the activity patterns observed in patients with epilepsy, an effective network model should be able to explain:

1. Normal and epileptiform states
2. Prototypical oscillations and bursts
3. Transitions between the states

From these properties a few general conclusions about the nature of the model can be determined. First, a model of neuronal population activity must be at least two dimensional to explain oscillations. Second, transitions between normal and epileptiform activity can be modeled by a bifurcation in a nonlinear dynamical system. Of course there are many bifurcations that could explain sudden onset and offset of seizure-like oscillations. Examples using the simplest candidate, co-dimension-1 bifurcations transitioning a system between steady state and oscillatory behavior and the sub- and supercritical Hopf bifurcations (Strogatz 1994), are shown in Fig. 5. In this figure, the two top panels show the bifurcation superimposed on seizure activity; the bottom panel indicates that in case of the subcritical scenario, the transition can also occur if the system exceeds the boundary between the basins of attractors (one attractor being the stable node and the other the stable limit cycle) (Milton and Jung 2003).

Some of the models employed in epilepsy research go beyond the minimalistic approach of two dimensions. The detailed simulation models with compartmental neuron models with realistic ion channels may have hundreds of parameters. Independent of the level of complexity of the network models, it is important to know if the neuron model itself is capable of oscillatory activity so that the individual network node can be a pacemaker for oscillation.

Node-Based Models Models built from cellular models have frequently been employed to study epileptiform behaviors in hippocampus and

neocortex (Lytton et al. 1997; Lytton and Sejnowski 1991; Lytton 2008; Traub and Llinas 1979; Traub et al. 1994; van Drongelen et al. 2004, 2005, 2006, 2007, 2008). In these models, excitatory and inhibitory parameters can be varied at individual or global levels while effects on neural synchrony and overall network activity can be determined. The advantage of this approach is that activity patterns can be directly linked to intrinsic membrane function and synaptic properties that can be modulated experimentally (van Drongelen et al. 2005) or used to evaluate anticonvulsant treatment. An example of the latter application of modeling for antipsychotic treatment was described by Siekmeier and van Maanen (2013). Ultimately, this type of result might help to establish a rational approach to anticonvulsant treatment.

An example of a node-based model is shown in Fig. 6a. This network model includes two different types of pyramidal neurons and four types of inhibitory cells. The currents generated by the individual nodes are used to simulate an EEG signal. Although the model creates a detailed overview of activity at both cellular and network levels, this detail also creates complexity that makes it difficult to interpret the findings. To gain a fundamental insight in the neuronal network processes in detailed simulations, one can average activities originating in different populations (Fig. 6c) (van Drongelen et al. 2006) or construct mathematical equivalents of such averaged activities (Fig. 6b) (Visser et al. 2010).

Population Models and Epileptiform

Activity Here, we examine the population models we described in Section 4 for their capability of generating seizure-like behavior. The Wilson–Cowan (1972) model is both nonlinear and two dimensional and is therefore capable of showing a range of behaviors that include limit cycles (Fig. 10) and transitions from stable behavior to an oscillatory one. The Wilson–Cowan model satisfies the three criteria of an effective network model for studying epilepsy described in the previous section. In addition, it is also a minimal model because the two dimensions (E and I ,

Epilepsy: Computational Models, Fig. 6 Model of neocortex. The detailed model (after van Drongelen et al. 2006) is outlined in diagram (a). The excitatory populations consist of superficial (*S_PYR*) and deep (*D_PYR*) pyramidal cells, and the inhibitory neuron type (*I*) consists of populations of basket cells (*B*) and chandelier cells (*CH*). The weighted sum of all soma currents is used as the “EEG” signal (top, panel a). The excitatory connections of the microcircuitry are shown in the left part and the inhibitory synapses in the right part of panel (a).

Panel (b) depicts a detail of the EEG during seizure-like oscillation in the “EEG” and the associated raster plots of the *S_PYR* and *D_PYR* populations. The simplified network version, after Visser et al. (2010), where only excitatory pyramidal cells and inhibitory neuronal populations are considered, is shown in the right part of panel (b). (c) The average membrane potentials of both pyramidal cell populations show that the activities of the deep *S_PYR* and *D_PYR* populations alternate during seizure-like oscillation (From van Drongelen (2013))

Epilepsy: Computational Models, Fig. 7

Bifurcations, caused by a gradually varying excitatory coupling (blue, top trace), creating a seizure-like epoch in population activity governed by the Wilson–Cowan equations (excitatory population – red and inhibitory population – green) (From van Drongelen (2013))

Eqs. 1, 2) are minimally required to include oscillation and the nonlinearity (sigmoids S_e and S_i) is essential for the existence of sudden transitions (bifurcations) between non-oscillatory and oscillatory states. An example of how a gradually changing excitatory coupling (represented by

constants c_1 and c_3 in Fig. 9) can cause sudden transitions of the population activity is depicted in Fig. 7. Interestingly, it can be seen that, depending on the initial state, oscillations may occur with both increasing and decreasing strength of the coupling (arrows, Fig. 7).

The modeling approach by Lopes da Silva et al. (1974) was used to formulate the Jansen neural mass model, which was later examined for epileptic behavior by Grimbert and Faugeras (2006). Several versions of neural mass models were recently investigated (Blenkinsop et al. 2012; Goodfellow et al. 2012; Touboul et al. 2011; Wendling and Chauvel 2008; Wendling et al. 2012). Because these neural mass models are at least two dimensional and nonlinear (e.g., see Eq. 6), they are capable of displaying transitions between activities associated with a stable node and oscillations or even chaotic behavior if they have three or more dimensions. The neural mass models by Freeman (1987) are capable of displaying these behaviors as well since they are both relatively high dimensional and nonlinear. However, due to Freeman's parameter choices, the isolated *K0* populations (Section 4.3.2) show stable behavior only. Using Freeman's choice of parameters, the model displays chaotic behavior similar to ongoing discharges during a seizure (Fig. 2c).

Linearized models do not support bifurcations and therefore fall short in explaining a critical aspect of epilepsy (seizure onset and offset). The linearized model of Nunez (1974, 1995) has this shortcoming. Nonetheless, it is useful to check if it supports oscillatory activity. First, the oscillatory activity can model ongoing seizure activity. Second, the point where an unstable oscillation arises in a linearized system is an indicator for a Hopf bifurcation in the full nonlinear model.

Conclusion

In the previous sections, a variety of modeling approaches used in neuroscience has been presented. As shown in Section 5, most models are capable of explaining aspects of epileptiform behavior. Interestingly, some of these explanations are counterintuitive (e.g., Lytton 2008; Ullah and Schiff 2009). Considering the rich repertoire of model behaviors, it is not surprising that a single approach to treatment, such as adjusting the excitation–inhibition balance, is likely to fail.

A common theme in the different models is that oscillatory behavior arises from the force term in the differential equations; in the neuronal networks, these force terms may represent membrane currents of the cells that create an oscillatory input and/or the properties of the network that embeds them. A logical next step would be to create a systematic summary of hypothetical mechanisms leading to epileptiform activity and to examine them in experimental models and clinical cases.

In general, the interest in and acceptance of modeling in neuroscience is growing (e.g., Abbott 2008; Destexhe and Sejnowski 2009). However, an important roadblock for the application of modeling is that, in part due to the complexity of the nervous system, there is little consensus amongst neuroscientists on what properties are to be considered critical in a theoretical approach. For this reason, traditionally, the neuroscientist prefers “realistic models” in which many experimental details are represented. Of course, in this sense, the skeptical neuroscientist is right that all models are wrong, i.e., no model fully captures reality, both by design and because some details are simply not known. To cite Rosenblueth and Wiener (1945), “the best material model for a cat is another, or preferably the same cat.” It is obvious that such a “best material model” is not the most helpful tool for a theoretical study of specific aspects of cat behavior because it clearly contains too much detail. Similarly, if one models traffic flow, one probably wouldn't include some details (e.g., color of the cars) while including others (e.g., number of traffic lanes between suburbs and industrial zones). Just like in physics, when modeling in biology, it is good to recall Einstein's dictum: “models should be as simple as possible, but not more so” (e.g., May 2004). Due to simplifications, models do not include all possible parameters, but they can nonetheless be very useful because they allow us to make predictions and they may generate uncluttered insight into the critical components of the underlying mechanisms of the modeled process. Of course, the above general statements are valid for modeling in neuroscience, whether we deal with models that describe the microscopic details of cellular function or ones that deal with the macroscopic

networks of billions of nerve cells in the human brain.

In spite of the necessary simplifications required in modeling, there are limitations in the models reviewed here; they neglect many aspects that play important roles. A critical part of the dynamics of neuronal networks is determined by synaptic plasticity, i.e., the change in network connection strength. These changes play a crucial role in the process of learning but, when pathologic, may also contribute to diseases such as epilepsy. It was more than a half century ago that Hebb (1949) recognized this and postulated his law. Hebb's law describes how synaptic coupling strength depends on local activity. It is often presented in a simplified form as: "neurons that fire together wire together." Much later, an experimental approach has confirmed the existence of activity-dependent plasticity at the level of the coupling between nerve cells, i.e., the synapse (e.g., Bi and Poo 2001; Woodin et al. 2003). Here, the plastic changes appeared to depend on the timing of the action potential (spike) activity of the pre- and postsynaptic neurons and are therefore also called spike-timing-dependent plasticity (STDP). STDP has been used in simulations to find appropriate synaptic strength (e.g., Izhikevich and Edelman 2008) effectively as a parameter estimation technique. It is fairly obvious that if connections between excitatory neurons that fire together also wire together (i.e., get strengthened), it represents a positive feedback mechanism, which may lead to instability and possibly seizure-like hyperactivity (Beenhakker and Huguenard 2009). Therefore, under normal physiological conditions, there must be additional mechanisms counteracting this positive feedback. Recently, an interesting attempt was made to analyze effects of plasticity of inhibitory synapses at the population level and successfully relate it to the network's balance between excitation and inhibition (Vogels et al. 2011). Since this model describes strengthening of the inhibitory connection, the instability issue does not arise here. Although plasticity is an important aspect of network behavior, the models reviewed here did not include it as one of the properties. Plasticity and many other aspects involved in nervous system

function, such as the role of glia (e.g., Volman et al. 2012), remain to be investigated.

Finally, one important conclusion is that there is not "a best approach" when modeling neural function. For example, nonlinear models can help us to understand specifics such as sudden transitions, but linear ones are more suitable to analyze subthreshold properties such as oscillation. The linearized versions of the models also make it easier to see similarities between the models across different levels of organization. Another example, complex models can be studied with simulations; they are more complete since they can deal with more parameters than the more abstract models used for mathematical analysis. However, both have a place and they can be complementary. Analysis of simplified mathematical models can generate fundamental insight in spite of the fact that they lack detail. Simulation can be too complex to directly generate such fundamental insight into the interaction of the ongoing processes, but they have the advantage to be closer to reality. This property appeals to the experimenter since it may produce data with a temporal-spatial resolution that isn't (yet) feasible experimentally. In this context, the ultimate goal in understanding neural networks in physiological and pathological states is to create a framework of experimental models, detailed simulations, and mathematical formalisms that allow us to understand and to predict dynamics of network activities including state transitions, i.e., results in one model can be used to inspire work in another type of model. In the case of analyzing a heterogeneous network disease such as epilepsy, modeling can provide an overview of hypothetical network mechanisms involved in ictal activity that can be employed as a guide for experimental and clinical investigation.

Equivalent Cylinder Model (Rall)

William R. Holmes

Department of Biological Sciences, Ohio University, Athens, OH, USA

Definition

The equivalent cylinder model is a means to reduce the complex branching structure of a dendritic tree to a simple cylinder by making a set of assumptions about the morphological and electrotonic properties of the dendrites, allowing tractable mathematical analyses that can provide useful insights into dendritic function.

Detailed Description

It is difficult to gain mathematical insight into the function of complex branched dendritic trees. Analysis requires that the cable equation be solved for each dendritic segment, given boundary conditions at the ends of the segments, plus an initial condition. Mathematical solutions become unwieldy, even with small numbers of dendritic segments (see ► [“Cable Equation”](#) entry). In 1962, Rall showed that with a few assumptions complex dendritic morphology could be reduced to a simple cylinder. This simplification is known as Rall’s equivalent cylinder model, and its application has provided much insight into neuron function.

Motivation

The mathematical arguments for reduction of a complex tree to a cylinder are given in Rall (1962a, b, 1964). Here, we will motivate this reduction by considering the simple case of a cable that branches into two daughter segments and showing how this can be reduced to a single cable (Fig. 1). The boundary condition at the end of the parent cable is a leaky end with a leak conductance G_L equal to the sum of the input conductances of the two daughter cables $G_1 + G_2$. Can we construct a single cable having input conductance $G_1 + G_2$ but also having the same diameter as the parent cable?

Recall that the input conductance, G_N , for a finite cylinder is (see entry ► “Cable Equation”)

$$G_N = G_\infty \tanh(l/\lambda) = \frac{\tanh(l/\lambda) d^{3/2}}{(2/\pi)\sqrt{R_{in}R_a}}.$$

Then, the sum of the input conductances of the two daughter cables (1 and 2 in Fig. 1) is

$$G_{N1} + G_{N2} = \frac{\pi}{2\sqrt{R_{in}R_a}} \left\{ \tanh\left(\frac{l_1}{\lambda_1}\right) d_1^{3/2} + \tanh\left(\frac{l_2}{\lambda_2}\right) d_2^{3/2} \right\}.$$

The input conductance of a single cable (3 in Fig. 1) is

$$G_{N3} = \frac{\pi}{2\sqrt{R_{in}R_a}} \left\{ \tanh\left(\frac{l_3}{\lambda_3}\right) d_3^{3/2} \right\}$$

Now suppose that R_m and R_a are the same in all cylinders and suppose that the electrotonic lengths of the cylinders are also the same, that is, $l_1/\lambda_1 = l_2/\lambda_2 = l_3/\lambda_3$. Then, $G_{N3} = G_{N1} + G_{N2}$

when $d_3^{3/2} = d_1^{3/2} + d_2^{3/2}$. This is called the “3/2 rule.” Thus, we can construct a single cable equivalent to two cables that also has the same diameter as the parent cable if the above assumptions are satisfied, the “3/2 rule” is satisfied, and d_3 equals the parent cable diameter.

Rall’s model

Rall (1962a, b, 1964) formally stated the conditions for the reduction of a branched dendritic tree to an equivalent cylinder as follows:

1. R_m and R_a are the same in all branches.
2. All terminal branches end with the same boundary condition (typically sealed end).
3. All terminal branches end at the same electrotonic distance, L , from $x = 0$ ($L = \sum \ell_i/\lambda_i$ is the same for all paths from $x = 0$ to all tips).
4. At every branch point, the diameter of the parent branch and its daughter branches must satisfy the relationship $d_{\text{parent}}^{3/2} = \sum d_{\text{daughters}}^{3/2}$.
5. Any dendritic input at a particular location must be delivered proportionally to all branches at the same electrotonic distance.

It should be noted that the daughter branches do not have to have the same diameters and that branches do not have to occur at the same electrotonic distances as shown, for convenience, by the symmetrical branching pattern in Fig. 2. Furthermore, the conditions above do not require branches to have the same physical length. Importantly, as can be seen from the equations following Fig. 1, the conditions above preserve

Equivalent Cylinder Model (Rall), Fig. 1 Can we replace segments 1 and 2 with an equivalent segment 3? G_L is the leak conductance at the end of the parent segment,

which must equal the sum of the input conductances of the daughter segments

Equivalent Cylinder Model (Rall), Fig. 2 Collapsing a dendritic tree to an equivalent cylinder. (Reproduced from Rall (1964))

both membrane area and input conductance of the original dendritic tree in the equivalent cylinder.

Do dendritic trees satisfy these constraints? The first condition that R_m and R_a are the same in all branches is reasonable as a first approximation although R_m and to a lesser extent R_a may be nonuniform. The second condition that all terminals end with the same boundary condition is reasonable. The third condition that all terminal branches end at the same electrotonic distance is likely to be violated. For example, the short basilar and long apical dendrites of pyramidal cells do not end at the same electrotonic distance. Motoneurons, which might appear at first glance to be good candidates for reduction to equivalent cylinders, have some branches terminating sooner than others, making a cylinder followed by a tapering cable a more appropriate representation. The fourth condition, the “3/2 rule”, was never claimed by Rall to be a rule of nature, but it happens to be satisfied in many dendritic trees, but also not in others. If the

“3/2 rule” is satisfied, there is impedance matching at branch points and no possible “reflections.” Voltage attenuation in the soma-to-distal direction proceeds smoothly. If the “3/2 rule” is not satisfied, then there are abrupt changes in attenuation at the branch point in the soma-to-distal direction. If daughter diameters are thinner than the “3/2 rule,” then voltage attenuation will be less steep before the branch point and more steep after the branch point than would be the case if the rule were satisfied. If daughter diameters are thicker than the “3/2 rule,” the opposite occurs; voltage attenuation will be steeper before the branch point and less steep after the branch point than when the “3/2 rule” is satisfied. This might have important implications for the relative effectiveness of inhibition delivered at the soma for changing the voltage at distances away from the soma. The fifth condition is required only when we consider inputs not at the soma. It is clearly not going to be satisfied generally. Nevertheless, superposition methods have been used in

conjunction with the equivalent cylinder model to deal appropriately with inputs on a single branch (Rall and Rinzel 1973; Rinzel and Rall 1974). Despite potential violations of the underlying assumptions, the equivalent cylinder model provides an excellent first approximation of the structure of dendritic trees and has proved to be an exceptional model for providing insights into neuronal function.

Definition

Information theory is a practical and theoretic framework developed for the study of communication over noisy channels. Its probabilistic basis and capacity to relate statistical structure to function make it ideally suited for studying information flow in the nervous system. It has a number of useful properties: it is a general measure sensitive to any relationship, not only linear effects; it has meaningful units which in many cases allow direct comparison between different experiments; and it can be used to study how much information can be gained by observing neural responses in single trials, rather than in averages over multiple trials. A variety of information-theoretic quantities are in common use in neuroscience (see entry ► [“Summary of Information-Theoretic Quantities”](#)). *Estimating* these quantities in an accurate and unbiased way from real neurophysiological data frequently presents challenges, which are explained in this entry.

Detailed Description

Information-Theoretic Quantities

Information theory provides a powerful theoretic framework for studying communication in a

quantitative way. Within the framework, there are many different quantities to assess different properties of systems, many of which have been applied fruitfully to analysis of the nervous system and neural communication. These include the entropy (H , which measures the uncertainty associated with a stochastic variable), mutual information (I , which measures the dependence relationship between two stochastic variables), and several more general divergence measures for probability distributions (Kullback–Leibler, Jensen–Shannon). For full definitions and details of these quantities, see the ► [“Summary of Information-Theoretic Quantities”](#) entry.

The Finite Sampling Problem

A major difficulty when applying techniques involving information-theoretic quantities to experimental systems is that they require measurement of the full probability distributions of the variables involved. If we had an infinite amount of data, we could measure the true stimulus–response probabilities precisely. However, any real experiment only yields a finite number

of trials from which these probabilities must be estimated. The estimated probabilities are subject to statistical error and necessarily fluctuate around their true values. The significance of these finite sampling fluctuations is that they lead to both statistical error (variance) and systematic error (called limited sampling bias) in estimates of entropies and information. This bias is the difference between the expected value of the quantity considered, computed from probability distributions estimated with N trials or samples, and its value computed from the true probability distribution. This is illustrated in Fig. 1, which shows histogram estimates of the response distribution for two different stimuli calculated from 40 trials per stimulus. While the true probabilities are uniform (dotted black lines), the calculated maximum likelihood estimates show some variation around the true values. This causes spurious differences – in this example, the sampled probabilities indicate that obtaining a large response suggests stimulus 1 is presented – which result in a positive value of the information. Figure 1c shows a histogram of information values obtained from many simulations of this system. The bias constitutes a significant practical problem because

Estimating Information-Theoretic Quantities, Fig. 1 The origin of the limited sampling bias in information measures. (a, b) Simulation of a toy uninformative neuron, responding on each trial with a uniform distribution of spike counts ranging from 0 to 9, regardless of which of the two stimuli ($S = 1$ in (a) and $S = 2$ in (b)) is presented. The black dotted horizontal line is the true response distribution; solid red lines are estimates sampled from 40 trials. The limited sampling causes the appearance of spurious differences in the two estimated conditional

response distributions, leading to an artificial positive value of mutual information. (c) The distribution (over 5,000 simulations) of the mutual information values obtained (without using any bias correction) estimating Eq. 1 from the stimulus–response probabilities computed with 40 trials. The dashed green vertical line indicates the true value of the mutual information carried by the simulated system (which equals 0 bits); the difference between this and the mean observed value (dotted green line) is the bias (Redrawn with permission from Ince et al. (2010))

its magnitude is often of the order of the information values to be evaluated and because it cannot be alleviated simply by averaging over many neurons with similar characteristics.

Direct Estimation of Information-Theoretic Quantities

The most direct way to compute information and entropies is to estimate the response probabilities as the experimental histogram of the frequency of each response across the available trials and then plug these empirical probability estimates into Eqs. 1, 2, and 3. We refer to this as the “plug-in” method.

The plug-in estimate of entropy is biased downward (estimated values are lower than the true value), while the plug-in estimate of information shows an upward bias. An intuitive explanation for why entropy is biased downward comes from the fact that entropy is a measure of variability. As we saw in Fig. 1, variance in the maximum likelihood probability estimates introduces extra structure in the probability distributions; this additional variation (which is dependent on the number of trials from the asymptotic normality of the ML estimate) always serves to make the estimated distribution less uniform or structured than the true distribution. Consequently, entropy estimates are lower than their true values, and the effect of finite sampling on entropies is a downward bias. For information, an explanation for why bias is typically positive is that finite sampling can introduce spurious stimulus-dependent differences in the response probabilities, which make the stimuli seem more discernible and hence the neuron more informative than it really is. Alternatively, viewing the information as a difference of unconditional and conditional entropies (first two expressions of Eq. (2) in ► “Summary of Information-Theoretic Quantities”), the conditional entropy for each stimulus value is estimated from a reduced number of trials compared to the noise entropy (only the trials corresponding to that stimulus), and so its bias is considerably larger. Since entropy is biased down and the conditional entropy term appears with a negative sign, this causes the upward bias in information.

In the above explanations for the source of the bias, the source is the variability in estimates of

the probability distributions considered. Variance in the maximum likelihood histogram estimators of the probabilities induces additional “noise” structure affecting the entropy and information values.

Asymptotic Estimates of the Limited Sampling Bias

To understand the sampling behavior of information and entropy better, it is useful to find analytical approximations to the bias. This can be done in the so-called asymptotic sampling regime. Roughly speaking, this is when the number of trials is “large.” More rigorously, the asymptotic sampling regime is defined as N being large enough that every possible response occurs many times: that is, $N_s P(r|s) \gg 1$ for each stimulus–response pair s, r such that $P(r|s) > 0$. In this regime, the bias of the entropies and information can be expanded in inverse powers of $1/N$ and analytical approximations obtained (Miller 1955; Panzeri and Treves 1996). The leading terms in the biases are, respectively,

$$\begin{aligned} \text{BIAS}[H(R)] &= \frac{-1}{2N \ln(2)} [\bar{R} - 1] \\ \text{BIAS}[H(R|S)] &= \frac{-1}{2N \ln(2)} \sum_s [\bar{R}_s - 1] \\ \text{BIAS}[I(S; R)] &= \frac{1}{2N \ln(2)} \left\{ \sum_s [\bar{R}_s - 1] - [\bar{R} - 1] \right\} \end{aligned} \quad (1)$$

Here, $\bar{R}_s$ denotes the number of relevant responses for the stimulus conditional response probability distribution $P(r|s)$ – i.e., the number of different responses r with nonzero probability of being observed when stimulus s is presented. $\bar{R}$ denotes the number of relevant responses for $P(r)$ – i.e., the number of different responses r with nonzero probability of being observed across all stimuli. In practice, $\bar{R}$ is usually going to be equal to the number of elements constituting the response space R . If a response never happens across all stimuli, it can be removed from the sum over r in the calculation of each entropy term and thus removed from the response set R . However, $\bar{R}_s$ may be different from $\bar{R}$ if some responses occur only with particular stimuli.

Although valid only in the asymptotic regime, Eq. 1 sheds valuable light on the key factors that control the bias. First, Eq. 1 shows that the bias of $H(R|S)$ is approximately S times bigger than that of $H(R)$. This means that in the presence of many stimuli, the bias of $I(S;R)$ is similar to that of $H(R|S)$. However, $I(S;R)$ is a difference of entropies, and its typical values are much smaller than those of $H(R|S)$. This implies that bias correction methods must be validated on the performance of information and not only on entropies because in many cases, the bias may be proportionally negligible for entropies but not the information. Second, Eq. 1 shows that the bias is small when the ratio $N_s/\bar{R}$ is big, i.e., more trials per stimulus than possible responses. This is because assuming that the number of trials per stimulus is approximately constant and $\bar{R}_s$ is approximately equal to $\bar{R}$, the bias of $H(R|S)$ is approximately

$\bar{R}/[2N_s \ln(2)]$. Thus, $N_s/\bar{R}$ is the crucial parameter for the sampling problem. For example, in the simulations of Fig. 2, with $\bar{R} = 2^8$, the bias of $I(S;R)$ became negligible for $N_s \geq 2^{13}$ (i.e., $N_s/\bar{R} \geq 32$). Second, Eq. 1 shows that even if N_s is constant, the bias increases with the number of responses $\bar{R}$. This has important implications for comparing neural codes. For example, a response consisting of a given number of spikes can arise from many different possible temporal patterns of spikes. Thus, $\bar{R}$ is typically much greater for a spike-timing code than for a spike count code, and it follows from Eq. 1 that the estimate of information conveyed by a spike-timing code is more biased than that measured for the same neurons through a spike count code. If bias is not eliminated, there is therefore a danger of concluding that spike timing is important even when it is not.

Estimating Information-Theoretic Quantities, Fig. 2 Performance of various bias correction methods. Several bias correction methods were applied to spike trains from eight simulated somatosensory cortical neurons. The information estimates (upper panels) and root mean square (RMS) error (lower panels) are plotted as a

function of the simulated number of trials per stimulus. (a) Mean $\pm$ SD (upper panel; over 50 simulations) and RMS error (lower panel) of $I(S;R)$. (b) Mean $\pm$ SD (upper panel; over 50 simulations) and RMS error (lower panel) of $I_{sh}(S;R)$

A further important feature of Eq. 1 is that although the bias is not the same for all probability distributions, in the asymptotic sampling regime, it depends on some remarkably simple details of the response distribution (the number of trials and the number of relevant responses). Thus, Eq. 1 makes it possible to derive simple rules of thumb for estimating the bias magnitude and compare the relative bias in different situations. As detailed in the next section, the simplicity of Eq. 1 can also be exploited in order to correct effectively for the bias (Panzeri and Treves 1996).

Bias Correction Methods

A number of techniques have been developed to address the issue of bias and allow much more accurate estimates of information-theoretic quantities than the “plug-in” method described above. Panzeri et al. (2007) and Victor (2006) provide a review of such methods, a selection of which is briefly outlined here.

Panzeri–Treves (PT)

In the so-called asymptotic sampling regime, when the number of trials is large enough that every possible response occurs many times, an analytical approximation for the bias (i.e., the difference between the true value and the plug-in estimate) of entropies and information can be obtained (Miller 1955; Panzeri and Treves 1996; Eq. 1). The value of the bias computed from the above expressions is then subtracted from the plug-in estimate to obtain the corrected value. This requires an estimate of the number of relevant responses for each stimulus, $\bar{R}_s$. The simplest approach is to approximate $\bar{R}_s$ by the count of responses that are observed at least once – this is the “naïve” count. However, due to finite sampling, this will be an underestimate of the true value. A Bayesian procedure (Panzeri and Treves 1996) can be used to obtain a more accurate value.

Quadratic Extrapolation (QE)

In the asymptotic sampling regime, the bias of entropies and information can be approximated as second-order expansions in $1/N$, where N is

the number of trials (Treves and Panzeri 1995; Strong et al. 1998). For example, for information

$$I_{\text{plugin}}(R; S) = I_{\text{true}}(R; S) + \frac{a}{N} + \frac{b}{N^2} \quad (2)$$

This property can be exploited by calculating the estimates with subsets of the original data, with $N/2$ and $N/4$ trials, and fitting the resulting values to the polynomial expression above. This allows an estimate of the parameters a and b and hence $I_{\text{true}}(S; R)$. To use all available data, estimates of two subsets of size $N/2$ and four subsets of size $N/4$ are averaged to obtain the values for the extrapolation. Together with the full length data calculation, this requires seven different evaluations of the quantity being estimated.

Nemenman–Shafee–Bialek (NSB)

The NSB method (Nemenman et al. 2002, 2004) utilizes a Bayesian inference approach and does not rely on the assumption of the asymptotic sampling regime. It is based on the principle that when estimating a quantity, the least bias will be achieved when assuming an a priori uniform distribution over the quantity. This method is more challenging to implement than the other methods, involving a large amount of function inversion and numerical integration. However, it often gives a significant improvement in the accuracy of the bias correction (Montani et al. 2007; Montemurro et al. 2007; Nemenman et al. 2008).

Shuffled Information Estimator (I_{sh})

Recently, an alternative method of estimating the mutual information has been proposed (Montemurro et al. 2007; Panzeri et al. 2007). Unlike the methods above, this is a method for calculating the information only and is not a general entropy bias correction. However, it can be used with the entropy corrections described above to obtain more accurate results. In brief, the method uses the addition and subtraction of different terms (in which correlations given a fixed stimulus are removed either by empirical shuffling or by marginalizing and then multiplying response probabilities) that do not change the information value in the limit of an infinite

number of trials, but do remove a large part of the bias for finite number of trials. This greatly reduces the bias of the information estimate, at the price of only a marginal increase of variance. Note that this procedure works well for weakly correlated data, which is frequently the case for simultaneously recorded neurons.

Examples of Bias Correction Performance

Figure 2a reports the results of the performance of bias correction procedures, both in terms of bias and root mean square (RMS) error, on a set of simulated spike trains from eight simulated neurons. Each of these neurons emitted spikes with a probability obtained from a Bernoulli process. The spiking probabilities were set equal to those measured, in the 10–15 ms poststimulus interval, from eight neurons in rat somatosensory cortex responding to 13 stimuli consisting of whisker vibrations of different amplitude and frequency (Arabzadeh et al. 2004). The 10–15 ms interval was chosen since it was found to be the interval containing highest information values. Figure 2a shows that all bias correction procedures generally improve the estimate of $I(S;R)$ with respect to the plug-in estimator, and the NSB correction is especially effective.

Figure 2b shows that the bias-corrected estimation of information (and RMS error; lower panel) is much improved by using $I_{sh}(R;S)$ rather than $I(R;S)$. The use of $I_{sh}(R;S)$ makes the residual errors in the estimation of information much smaller and almost independent from the bias correction method used. Taking into account both bias correction performance and computation time, for this simulated system, the best method to use is the shuffled information estimator combined with the Panzeri–Treves analytical correction. Using this, an accurate estimate of the information is possible even when the number of samples per stimulus is R , where R is the dimension of the response space.

It should be noted that while bias correction techniques such as those discussed above are essential if accurate estimation of the information is required, whether to employ them depends upon the question being addressed. If the aim is quantitative comparison of information values

between different experiments, stimuli, or behaviors, they are essential. If instead the goal is simply to detect the presence of a significant interaction, the statistical power of information as a test of independence is greater if the uncorrected plug-in estimate is used (Ince et al. 2012). This is because all the bias correction techniques introduce additional variance; for a hypothesis test which is unaffected by underlying bias, this variance reduces the statistical power.

Information Component Analysis Techniques

The principal use of information theory in neuroscience is to study the neural code – and one of the commonly studied problems in neural coding is to take a given neurophysiological dataset and to determine how the information about some external correlate is represented. One way to do this is to compute the mutual information that the neural responses convey on average about the stimuli (or other external correlate), under several different assumptions about the nature of the underlying code (e.g., firing rate, spike latency). The assumption is that if one code yields substantially greater mutual information, then downstream detectors are more likely to be using that code (the *efficient coding hypothesis*).

A conceptual improvement on this procedure, where it can be done, is to take the total information available from all patterns of spikes (and silences) and to break it down (mathematically) into components reflecting different encoding mechanisms, such as firing rates and pairwise correlations (Panzeri et al. 1999; Panzeri and Schultz 2001). One way to do this is to perform an asymptotic expansion of the mutual information, grouping terms in such a way that they reflect meaningful coding mechanisms.

Taylor Series Expansion of the Mutual Information

A Taylor series expansion of the mutual information is one such approach. For short time windows (and we will discuss presently what “short”

means), the mutual information can be approximated as

$$I(R;S) = TI_t + \frac{T^2}{2}I_{tt} + \dots \quad (3)$$

where the subscript t indicates the derivative with respect to the time window length T . For time windows sufficiently short that only a pair of spikes is contained within the time window (either from a population of cells or from a single spike train), the first two terms are all that is needed. If the number of spikes exceeds two, it may still be a good approximation, but higher-order terms would be needed to capture all of the information. One possibility is that Eq. 3 could be extended to incorporate higher-order terms; however, we have instead found it better in practice to take an alternative approach (see next section).

With only a few spikes to deal with, it is possible to use combinatorics to write out the expressions for the probabilities of observing different spike patterns. This was initially done for the information contained in the spikes fired by a small population of cells (Panzeri et al. 1999) and then later extended to the information carried by the spatiotemporal dynamics of a small population of neurons over a finite temporal word length (Panzeri and Schultz 2001). In the former formulation, we define $\bar{r}_i(s)$ to be the mean response rate (number of spikes in T divided by T) of cell i (of C cells) to stimulus s over all trials where s was presented. We then define the signal cross-correlation density to be

$$v_{ij} = \frac{\langle \bar{r}_i(s) \bar{r}_j(s) \rangle_s}{\langle \bar{r}_i(s) \rangle_s \langle \bar{r}_j(s) \rangle_s} - 1 \quad (4)$$

This quantity captures the correlation in the mean response profiles of each cell to different stimuli (e.g., correlated tuning curves). Analogously, we define the noise cross-correlation density to be

$$\gamma_{ij}(s) = \frac{r_i(s)r_j(s)}{\bar{r}_i(s)\bar{r}_j(s)} - 1 \quad (5)$$

The mutual information $I(R;S)$ can then be written as the sum of four components,

$$I = I_{\text{lin}} + I_{\text{sig-sim}} + I_{\text{cor-ind}} + I_{\text{cor-dep}}. \quad (6)$$

with the first component

$$I_{\text{lin}} = T \sum_{i=1}^C \left\langle \bar{r}_i(s) \log_2 \frac{\bar{r}_i(s)}{\langle \bar{r}_i(s') \rangle_{s'}} \right\rangle_s \quad (7)$$

capturing the rate component of the information, i.e., that which survives when there is no correlation between cells (even of their tuning curves) present at all. This quantity is positive semi-definite and adds linearly across neurons. It is identical to the “information per spike” approximation calculated by a number of authors (Skaggs et al. 1993; Brenner et al. 2000; Sharpee et al. 2004). $I_{\text{sig-sim}}$ is the correction to the information required to take account of correlation in the tuning of individual neurons or *signal similarity*:

$$I_{\text{sig-sim}} = \frac{T^2}{2 \ln 2} \sum_{i=1}^C \sum_{j=1}^C \langle \bar{r}_i(s) \rangle_s \langle \bar{r}_j(s) \rangle_s \left[v_{ij} + (1 + v_{ij}) \ln \left(\frac{1}{1 + v_{ij}} \right) \right] \quad (8)$$

This is negative semi-definite. $I_{\text{cor-ind}}$ is the effect on the transmitted information of the average level of noise correlation (correlation at fixed stimulus) between neurons:

$$I_{\text{cor-ind}} = \frac{T^2}{2} \sum_{i=1}^C \sum_{j=1}^C \langle \bar{r}_i(s) \bar{r}_j(s) \gamma_{ij}(s) \rangle_s \log_2 \left(\frac{1}{1 + v_{ij}} \right) \quad (9)$$

$I_{\text{cor-ind}}$ can take either positive or negative values. $I_{\text{cor-dep}}$ is the contribution of stimulus dependence in the correlation to the information – as would be present, for instance, if synchrony was modulated by a stimulus parameter:

$$I_{\text{cor-dep}} = \frac{T^2}{2} \sum_{i=1}^C \sum_{j=1}^C \left\langle \bar{r}_i(s) \bar{r}_j(s) (1 + \gamma_{ij}(s)) \log_2 \left[\frac{\langle \bar{r}_i(s') \bar{r}_j(s') \rangle_s (1 + \gamma_{ij}(s))}{\langle \bar{r}_i(s') \bar{r}_j(s') \rangle_{s'} (1 + \gamma_{ij}(s'))} \right] \right\rangle_s \quad (10)$$

An application of this approach to break out components reflecting rate and correlational

Estimating Information-Theoretic Quantities, Fig. 3 Information component analysis of simulated data (for a five-cell ensemble). (a) Poisson cells, with the only difference between the stimuli being firing rate. (b) Integrate-and-fire cells, with common input due to sharing of one third of connections, resulting in a cross-correlogram as depicted in (c) contribution to the information from $I_{\text{cor}} - \text{ind.}$ (d) Integrate-and-fire cells with

two of the five cells increasing their correlation due to increased shared input, for one of the stimuli, where the others remain randomly correlated, leading to cross-correlograms shown in panel (e). Firing rates are approximately balanced between the two stimuli. This results in a substantial contribution to the information from the stimulus-dependent correlation component, $I_{\text{cor}} - \text{dep.}$ (From Panzeri et al. 1999 with permission)

coding is illustrated in Fig. 3 by application to simulated spike trains with controlled correlation. This approach has been used by a number of authors to dissect out contributions to neural coding (e.g., Scaglione et al. 2008).

This approach extends naturally to the consideration of temporal correlations between spike times within a spike train (Panzeri and Schultz 2001). Note that the Taylor series approach can be applied to the entropy as well as the mutual information – this was used to break out the effect of spatiotemporal correlations on the entropy of a small population of neural spike trains (Schultz and Panzeri 2001). While the Taylor series approach can be extremely useful in teasing out contributions of different mechanisms to the transmission of information, it is not recommended as a method for estimation of the total information, as the validity of the approximation can break down quickly as the time

window grows beyond that sufficient to contain more than a few spikes from the population. It is however useful as an additional inspection tool after the total information has been computed, which allows the information to be broken down into not only mechanistic components but also their contributions from individual cells and time bins (for instance, by visualizing the quantity after the summations in Eq. 10 as a matrix).

A More General Information Component Analysis Approach

A limitation of the Taylor series approach is that it is restricted to the analysis of quite short time windows of neural responses. However, an exact breakdown approach allowed a very similar information component approach to be used (Pola et al. 2003). In this approach, we consider a population response (spike pattern) $\mathbf{r}$ and define the normalized noise cross-correlation to be

$$\gamma(\mathbf{r}|s) = \begin{cases} \frac{P(\mathbf{r}|s)}{P_{\text{ind}}(\mathbf{r}|s)} - 1 & \text{if } P_{\text{ind}}(\mathbf{r}|s) \neq 0 \\ 0 & \text{if } P_{\text{ind}}(\mathbf{r}|s) = 0 \end{cases} \quad (11)$$

where the marginal distribution

$$P_{\text{ind}}(\mathbf{r}|s) = \prod_{c=1}^C P(r_c|s). \quad (12)$$

Compare the expressions in Eqs. 5 and 12. Similarly, the signal correlation becomes

$$v(\mathbf{r}) = \begin{cases} \frac{P_{\text{ind}}(\mathbf{r})}{\prod_c P(r_c)} - 1 & \text{if } \prod_c P(r_c) \neq 0 \\ 0 & \text{if } \prod_c P(r_c) = 0 \end{cases} \quad (13)$$

Using these definitions, the information components can now be written exactly (without the approximation of short time windows) as

$$I_{\text{lin}} = \sum_c \sum_{r_c} \left\langle P(r_o|s) \log_2 \frac{P(r_c|s)}{P(r_c)} \right\rangle_s \quad (14)$$

$$I_{\text{sig-sim}} = \frac{1}{\ln 2} \sum_r \left(\prod_c P(r_c) \right) \quad (15)$$

$$\left[v(\mathbf{r}) + (1 + v(\mathbf{r})) \ln \left(\frac{1}{1 + v(\mathbf{r})} \right) \right]$$

$$I_{\text{cor-ind}} = \sum_r \langle P_{\text{ind}}(\mathbf{r}|s) \gamma(\mathbf{r}|s) \rangle_s \log_2 \left(\frac{1}{1 + v(\mathbf{r})} \right) \quad (16)$$

$$I_{\text{cor-dep}} = \sum_r \left\langle P_{\text{ind}}(\mathbf{r}|s) (1 + \gamma(\mathbf{r}|s)) \log_2 \frac{\langle P_{\text{ind}}(\mathbf{r}|s') \rangle_s (1 + \gamma(\mathbf{r}|s))}{\langle P_{\text{ind}}(\mathbf{r}|s') (1 + \gamma(\mathbf{r}|s)) \rangle_s} \right\rangle_s \quad (17)$$

This latter component is identical to the quantity “ ΔI ” introduced by Latham and colleagues (Nirenberg et al. 2001) to describe the information lost due to a decoder ignoring correlations. It is zero if and only if $P(s|\mathbf{r}) = P_{\text{ind}}(s|\mathbf{r})$ for every s and $\mathbf{r}$.

The expressions shown above are perhaps the most useful description for obtaining insight into the behavior of the information components under different statistical assumptions relating to the neural code; however, they are not necessarily the best way to *estimate* the individual components. However, the components can also be written as a sum of entropies and entropy-like quantities, which can then be computed using the entropy estimation algorithms described earlier in this entry (Pola et al. 2003; Montani et al. 2007; Schultz et al. 2009). Note that as shown by Scaglione and colleagues (Scaglione et al. 2008, 2010), the components in Eqs. 14, 15, 16, and 17 can, under appropriate conditions, be further decomposed to tease apart the relative role of

autocorrelations (spikes from the same cells) and cross-correlations (spikes from different cells).

Maximum Entropy Approach to Information Component Analysis

The conceptual basis of the information component approach is to make an assumption that constrains the statistics of the response distribution $P(\mathbf{r}|s)$, compute the mutual information subject to this assumption, and, by evaluating the difference between this and the “full” information, calculate the contribution to the information of relaxing this constraint. By making further assumptions, the contributions of additional mechanisms can in many cases be dissected out hierarchically. As an example, by assuming that the conditional distribution of responses given stimuli is equal to the marginal distribution $P(\mathbf{r}|s) = P_{\text{ind}}(\mathbf{r}|s)$ and substituting in to the mutual information equation, one can define an information component I_{ind} . This component can then be further broken up

$$I_{\text{ind}} = I_{\text{lin}} + I_{\text{sig-sim}}. \quad (18)$$

with I_{lin} and $I_{\text{sig-sim}}$ as defined in the previous section. The correlational component, I_{cor} , is then just the difference between I_{ind} and the total mutual information. This can also be further broken up as

$$I_{\text{cor}} = I_{\text{cor-ind}} + I_{\text{cor-dep}}. \quad (19)$$

This approach can be extended further. For instance, the assumption of a Markov approximation can be made, with a memory extending back q timesteps, and the information computed under this assumption (Pola et al. 2005). More generally, any simplified model can be used, although the maximum entropy models are of special interest (Montemurro et al. 2007; Schaub and Schultz 2012)

$$P_{\text{simp}}(\mathbf{r}|\mathbf{s}) = \frac{1}{Z} \exp \left\{ \lambda_0 - 1 + \sum_{i=1}^m \lambda_i g_i(\mathbf{r}) \right\} \quad (20)$$

with parameters λ_i implementing a set of constraints reflecting assumptions made about what are the important (non-noise) properties of the empirical distribution and the partition function Z ensuring normalization. An example of this is the Ising model, which has been used with some success to model neural population response distributions (Schneidman et al. 2006; Shlens et al. 2006; Schaub and Schultz 2012). Estimation of the Ising model for large neural populations can be extremely computationally intensive if brute force methods for computing the partition function are employed; however, mean field approximations can be employed in practice with good results (Roudi et al. 2009; Schaub and Schultz 2012).

Binless Methods for Estimating Information

In applications in neuroscience, typically at least one of the random variables (stimuli or responses) is discrete, and thus the approach of discretizing

one or more of the variables is often taken. However, where stimuli and responses are both continuous (an example might be local field potential responses to a white noise sensory stimulus), it may be advantageous to take advantages of techniques better suited to continuous signals, such as kernel density estimators (Moon et al. 1995), nearest neighbor estimators (Kraskov et al. 2004), or *binless* metric space methods (Victor 2002).

Calculation of Information-Theoretic Quantities from Parametric Models

An alternative to measuring information-theoretic quantities directly from observed data is to fit the data to a model and then to either analytically or numerically (depending upon the complexity of the model) compute the information quantity from the model. Examples include analytical calculations of the information flow through models of neural circuits with parameters fit to anatomical and physiological data (Treves and Panzeri 1995; Schultz and Treves 1998; Schultz and Rolls 1999) and parametric fitting of probabilistic models of neural spike firing (Paninski 2004; Pillow et al. 2005, 2008), of spike count distributions (Gershon et al. 1998; Clifford and Ibbotson 2000), or of neural mass signals (Magri et al. 2009). It should come as no surprise that “there is no free lunch,” and although in principle information quantities can be computed exactly under such circumstances, the problem is moved to one of assessing model validity – an incorrect model can lead to a bias in either direction in the information computed.

Estimation of Neuronal Firing Rate

Shigeru Shinomoto

Department of Physics, Kyoto University, Kyoto, Japan

Synonyms

Bayesian estimation; Firing frequency; Kernel smoother; PSTH; Spike rate; Time histogram

Definition

Neuronal firing rate is defined as the frequency at which a neuron discharges short-duration

electrical pulses called firings or spikes, measured as number of spikes per second [sp/s] or hertz [Hz]. Because the duration of each electrical discharge is typically much shorter than interspike intervals, a spike is often idealized as a point event on the time axis. The temporal occurrence of neuronal spikes is irregular and nonreproducible even under identical stimuli. In principle, such randomness can be removed by collecting a huge number of spike trains from repeated trials and constructing a histogram of arbitrarily fine resolution for the superimposed data. However, in practice, experiments are conducted with a small number of trials over short periods during which neuronal conditions may not alter significantly. To obtain reasonable estimates from limited number of data, inferential statistics is required.

Detailed Description

Here we introduce standard rate estimators such as the histogram, kernel smoother, and Bayesian method, with instructions for selecting their binsize, bandwidth, and hyperparameters (Fig. 1).

These optimization methods assume an inhomogeneous Poisson process whereby spikes are drawn independently from some underlying rate. This assumption holds if numerous independent spike trains are superimposed (Snyder 1975; Daley and Vere-Jones 2003), but is not necessarily appropriate for analyzing one or a few spike trains. We also introduce newer methods applicable to such non-Poisson firings.

Histogram Method

A peristimulus time histogram (PSTH) is constructed by aligning spike trains at the onset of a stimulus or certain behavioral condition and drawing tabular rectangles whose height equals the number of spikes counted in each bin (Gerstein and Kiang 1960; Abeles 1982). Each ordinate should be rescaled by dividing the spike count by the binsize and number of trials, so that its average height represents the firing rate per trial. For a

Estimation of Neuronal Firing Rate, Fig. 1 A spike train derived from the underlying rate and optimal histogram, kernel density estimate, and Bayesian estimate

obtained using web-applications provided in <http://www.ton.scphys.kyoto-u.ac.jp/~shino/toolbox/english.htm>

Estimation of Neuronal Firing Rate, Fig. 2 Time histograms constructed with small, optimal, and large bin sizes

given set of spike trains, different binsizes lead to different PSTH shapes. If the binsize is very large/small, the histogram may become too flat/spiky to represent the temporal modulation (Fig. 2). There should be an appropriate binsize for a given set of spike times, based on the goodness of fit of a PSTH to the (unknown) underlying rate.

Here we consider selecting the binsize by minimizing the mean integrated squared error (MISE) (Rudemo 1982; Shimazaki and Shinomoto 2007; Shinomoto 2010) between the histogram $\hat{\lambda}(t)$ and unknown underlying rate $\lambda(t)$, defined by $MISE \equiv \frac{1}{T} \int_0^T E(\hat{\lambda}(t) - \lambda(t))^2 dt$, where T is the entire observation interval and E refers to taking

expectation over all possible spike trains that can be realized under given rate. The height of the histogram $\hat{\lambda}(t)$ is given by the number of spikes k counted in each bin divided by the binsize Δ and number of trials n . Using the bias-variance decomposition, it was proven that the MISE can be expressed in terms of the spike count k as

$$MISE = \frac{2\langle V(k) \rangle - \langle E(k - E(k))^2 \rangle}{(n\Delta)^2} + \text{constant},$$

where V and $\langle \cdot \rangle$ refer to taking variance over all possible spike trains and averaging across all bins, respectively. Though the variance cannot be

estimated from a single spike train, if spikes are derived independently, the spike count in each bin follows the Poisson relationship $V(k) = E(k)$; as a result, this part becomes an observable quantity. The second term on the right-hand side is rewritten as $\langle E(k - E\langle k \rangle)^2 \rangle = \langle E(k - \langle k \rangle)^2 \rangle + \langle V(k) \rangle / M$, where M represents the total number of bins. Thus, the MISE can be expressed solely in terms of the expectation of spike counts,

$$\text{MISE} = \frac{E\left(2\langle k \rangle(1 - 1/2M) - \langle (k - \langle k \rangle)^2 \rangle\right)}{(n\Delta)^2} + \text{constant}.$$

Representing the expectation E as a single spike train and ignoring the correction of $1/2M$, we obtain $\text{MISE} = \frac{2\bar{k} - v}{(n\Delta)^2} + \text{constant}$ where $\bar{k} \equiv \sum k_i / M$ is the mean spike count and $v \equiv \sum (k_i - \bar{k})^2 / M$ is the spike count variance across all M bins, both of which depend on the bin size Δ . Thus, a histogram can be optimized for any given spike data, simply by minimizing this MISE.

Kernel Smoothing Method

The rate profile can also be obtained by convoluting the density kernel. $d_\Delta(t)$ with spike times

$$\{t_j\} \equiv \{t_1, t_2, \dots, t_K\}: \hat{\lambda}(t) = \frac{1}{n} \sum_{j=1}^K d_\Delta(t - t_j)$$

where n is the number of trials and K is the total number of spikes contained in all trials. The density kernel can be a rectangular boxcar function, two-sided exponential function, or Gaussian function, satisfying the normalization, $\int d_\Delta(t) dt = 1$, and possessing a finite bandwidth, $\int t^2 d_\Delta(t) dt = \Delta^2$. Generally the kernel method yields a smoother estimation than the histogram, but the goodness of fit still depends on the bandwidth Δ . The bandwidth may also be selected under the MISE minimization principle. Under the Poisson assumption, the MISE is obtained (Shimazaki and Shinomoto 2010) as follows

$$\begin{aligned} \text{MISE} &= \frac{1}{n^2} \\ &\times \left(\sum_{i,j} \phi_\Delta(t_i - t_j) - 2 \sum_{i \neq j} d_\Delta(t_i - t_j) \right) \\ &+ \text{constant}, \end{aligned}$$

where

$$\phi_\Delta(t_i - t_j) \equiv \int d_\Delta(t - t_i) d_\Delta(t - t_j) dt.$$

For a Gaussian kernel, $d_\Delta(t) \equiv (1/\sqrt{2\pi}\Delta) \exp(-t^2/(2\Delta^2))$, the convoluted function is given as $\phi_\Delta(t) \equiv (1/\sqrt{2\pi}\Delta) \exp(-t^2/(4\Delta^2))$.

The abovementioned optimization method determines a single fixed bandwidth by assuming stationary rate fluctuation. However, neurons often exhibit abrupt increase of spikes followed by gradual decrease. In such a case, a small bandwidth may detect the sharp rise, but it may add unnecessary fluctuation in the relaxation stage, whereas a large bandwidth is suitable for expressing the smooth relaxation, but it may blur the rise in firing rate. There are several methods that consider such non-stationary data with adaptive time-modulated hyperparameters; Abramson's adaptive kernel method modulates the bandwidths adaptively at the sample point (Abramson 1982); the locfit algorithm fits a polynomial to a log-density function under the principle of maximizing a locally defined likelihood (Loader 1999); BARS is a spline-based adaptive regression method on exponential family response model, expected to smooth data without missing its abrupt change (DiMatteo et al. 2001; Kass et al. 2003). Comparison of the model performances is given in Shimazaki and Shinomoto (2010).

Bayesian Methods

In the inhomogeneous Poisson process, spikes are drawn independently from the underlying spiking rate $\lambda(t)$. The probability of spiking at $\{t_j\}$ is given by Cox and Lewis (1966) and Daley and Vere-Jones (2003)

$$p(\{t_j\}|\lambda(t)) = \left(\prod_{j=1}^K \lambda(t_j) \right) \exp \left(- \int_0^T \lambda(t) dt \right).$$

The underlying rate is inferred from the given data using Bayes' formula:

$$p(\lambda(t)|\{t_j\}) = \frac{p(\{t_j\}|\lambda(t))p(\lambda(t))}{p(\{t_j\})}.$$

Here we give the prior distribution functional that penalizes the large gradient in the rate, i.e.,

$$p(\lambda(t)) \propto \exp \left(-\beta \int_0^T \left(\frac{d\lambda}{dt} \right)^2 dt \right),$$

where the hyperparameter β represents the degree of flatness of the rate, which determines the jaggedness of the estimated rate. The hyperparameter may be selected by maximizing the marginal likelihood, given by the functional integration over all possible rate processes

$$p_\beta(\{t_j\}) = \int D\{\lambda(t)\} p(\{t_j\}|\lambda(t)) p(\beta)(\lambda(t)),$$

using the expectation and maximization (EM) method (Smith and Brown 2003; Shimokawa and Shinomoto 2009). With the determined hyperparameter, we obtain the maximum *a posteriori* (MAP) estimate of the rate $\hat{\lambda}(t)$, which maximizes the posterior distribution functional.

Extension of the Method Toward Non-Poisson Data

All abovementioned optimization methods are derived under the Poisson assumption. However, neurons express non-Poissonian features in their firing patterns; in particular, spike occurrence is influenced by preceding spiking events (Shinomoto et al. 2009). Thus, the optimization methods should be revised if one requires to estimate the rate of one or a few spike trains.

The histogram optimization method was extended to accommodate non-Poisson data, by replacing the equality between the spike count variance and mean by the Fano factor (Omi and Shinomoto 2011). The Fano factor approximately equals the square of the coefficient of variation of interspike intervals obtained from a single spike train (Cox 1962). A similar idea is applicable to the Bayesian rate estimation method. It was found that the rate estimation is significantly improved or the temporal resolution of the rate profile becomes finer, if the spike train is more regular than Poisson randomness (Cunningham et al. 2008; Koyama et al. 2013).

[Evolutionary strategies/genetic algorithms](#)

Definition

Evolutionary algorithms are a family of computational approaches inspired by natural selection

that address two main topics: developing algorithms for optimization and understanding biological evolution. The former use is the more common, evolutionary algorithms being one of the main tools for parallel optimization. Indeed, they have been applied successfully to diverse optimization problems such as modeling the electrical properties of neurons (Achard and De Schutter 2006; Druckmann et al. 2007; Keren et al. 2009; Smolinski and Prinz 2009), automated writing of programs for specific tasks, and financial market modeling.

Detailed Description

The idea that natural evolution could be used as an inspiration for optimization algorithms rose in the 1950s and 1960s (Rechenberg 1965; Fogel et al. 1966; Schwefel 1977). One of the most widespread forms, genetic algorithms (GAs), was invented by J. Holland in the 1960s. At their core these algorithms are computational simulations of a simplified version of evolution: a set of individuals (a population) evolves over numerous iterations (generations) whereby the next population is determined by replicating successful solutions (individuals with high fitness) and adjusting them stochastically (mutation, crossover). There are many forms of evolutionary algorithms and their taxonomy goes well beyond the scope of this brief article. Here, we will focus mainly on genetic algorithms.

Genetic algorithms have a number of properties that make them useful optimization tools. First, they simultaneously consider a large set of solutions, thereby alleviating to some extent the problem of optimization converging on only locally optimal solutions. Since most real-world problems involve nonlinearity and complex variable interactions, there are often multiple solutions that are only local maxima, i.e., locally optimal but are not the true global optimum. Being able to simultaneously consider a large number of solutions helps to mitigate this problem since the multiple parallel solutions considered typically span a wide range of parameters, affording a more global view of the problem and

revealing the nature of local minima. Second, the formulation of genetic algorithms makes them easily parallelizable. Accordingly, they can take advantage of the increasingly common high-performance computing clusters that have dozens or even hundreds of parallel processors.

The basic operation of genetic algorithm optimization is straightforward consisting of several simple steps. Starting with an initial set of solutions, one performs multiple iterations of evaluating the current set of solutions. Then the best solutions are chosen to form the basis of the next set of solutions, in an iterative attempt to find ever better solutions (see pseudo code in Table 1). Below we briefly describe each step:

- *Evaluation (fitness selection)* – in the case of optimization, this step is typically comprised of evaluating the function to be optimized for every solution in the population. This step can be performed very effectively using parallel computing clusters since the evaluation of each solution is completely independent of the others.
- *Propagation (reproduction)* – the goal of this operation is to make multiple duplicates of successful solutions (which will later be perturbed) and eliminate poorer solutions in an effort to move towards more valuable solutions in the next generation. In the case of optimization, more successful solutions are

simply solutions with a higher fitness (or lower error value). One straightforward approach for propagating successful solution is to stochastically select which solutions will propagate according to a probability proportional to the solution’s success.

- *Evolution (mutation, crossover)* – the goal is to semi-randomly change parameter values in an effort to stochastically strike upon a more successful solution. This operation represents the main search aspect of the algorithm. Often the evolution is performed through one or both of the following operators: mutation and crossover. Mutation in principle consists simply of jittering the parameter values. Crossover operators are analogous to genetic crossover in that two “parent” solutions are combined to create a new solution that is different from either parent.

Genetic Algorithms in Practice: A Simple Binary Value Genetic Algorithm

To better understand the nature of genetic algorithms, we describe in more detail a specific implementation of a genetic algorithm, a simple binary value genetic algorithm (Holland 1992).

Consider the very simple problem of optimizing the function:

F = sin (X + Y/2) + Y - 0.5

The problem has two parameters: *X* and *Y*, and we seek the values of these parameters that maximize the function *F* (Fig. 1a). Note that this function is trivial to optimize without genetic algorithms and is merely used as a simple example. Below, we describe the steps involved in running the genetic algorithm on this simple problem.

Representing a Solution

In the original genetic algorithm formulation a binary string represents each parameter value, and an ordered collection of these binary strings represents the full information that defines a

Evolutionary Algorithms, Table 1 Genetic algorithms repeatedly test a set of solutions (a population) through multiple iterations (generations). In each iteration all solutions are evaluated. Then the successful solutions are used to generate the basis for the next iteration of solutions. These tentative solutions are then perturbed stochastically to yield the next iteration of solutions and the cycle continues until it reaches a predetermined number of generations

Evolutionary Algorithms, Fig. 1 Schematic representation of binary valued genetic algorithm steps. (a) Fitness function. In this example, a simple function of two parameters (X , Y) is optimized. (b) Genomes and populations. A genetic algorithm evaluates in parallel a number of tentative solutions. Solutions are referred to as organisms and the set of solutions as a population. In a binary genetic algorithm the parameter values of each solution are expressed as a string of binary numbers (depicted in squares) and referred to as an organism's genome. (c) Organism fitness. Each organism in the population is assigned a fitness value by the optimization objective. (d) Population propagation. In order to select which of the organisms will form the basis of the population in the next generation (i.e., evaluation iteration), a propagation

procedure is defined. In this case *roulette-wheel* sampling assigns a part of the range of a random variable to each solution in a manner proportional to the relative fitness of that solution. Letters denote which part of the 0–1 range is associated with each solution. Numbers correspond to the range limits for each solution. (e) New generation basis. After the propagation procedure a basis for the next generation's population is defined which will then be transformed by the genetic operators: mutation and crossover. (f) Mutation. Solutions are stochastically perturbed, in this case by a probability of flipping each bit of the genome. (g) Crossover. This genetic operator combines two solutions by joining a portion of each genome, defined by the cross-over point, from each of the two

particular solution (Fig. 1b). The analogy to biology is that each parameter corresponds to a gene, with the different values being different alleles; the entire collection of parameter values is an organism's genome.

For instance, the binary string 110 represents the value 6. Therefore, the parameter values of organism A in our example are $X = 6$, $Y = 4$ (Fig. 1b). More generally, instead of having a direct binary encoding as we have here, the binary values can be

used to represent values within a given range. A common approach is to divide the parameter range by the maximum value afforded by the binary string and have the binary number represent the fraction times the binary number value. For instance, a 3-long binary string encodes one of eight values: (0, 1, 2, 3, 4, 5, 6, 7). Therefore, if the parameter range for a particular parameter was a minimum of 1 and a maximum of 2, the value 000 would represent $1 + 0/7$, i.e., 1; the string 111 would represent $1 + 7/7$, i.e., 2; and the value 110 would represent $1 + 6/7$. Defining r as the range of the parameter value (e.g., 1–2), this can be written as:

$$X = \min(r) + (\text{binary value}) * (\max(r) - \min(r)) / (\text{number of possible binary values} - 1)$$

Initializing the Population

In order to begin running the algorithm, an initial population, i.e., an initial set of tentative solutions, needs to be generated. Typically, this is performed by setting random values to the initial parameter values. In our example one can accomplish this by flipping a coin for each binary value in the genome of each solution.

Evaluating a Solution

In this step we evaluate the fitness of all the organisms in the current population. In the case of the problem we chose, the fitness of an organism can be computed directly from its definition simply by evaluating the function F for the X and Y values defined by each solution (Fig. 1a, b) with little difficulty or computational cost (Fig. 1c). However, in more complex, real-world problems, the parameter values typically correspond to properties of some model that will then be simulated and the results of the simulation evaluated. Accordingly, solution evaluation in the more generic case is the computationally expensive part of the algorithm. Fortunately, as mentioned above it can be performed independently in parallel for each organism.

Propagating Solutions

In this step the old population (Fig. 1b, c) is transformed into a basis for the new population

(Fig. 1e). The general goal of this step is to have solutions that were found to be more successful take up a larger fraction of the new population. A simple form of propagation capturing this notion is “roulette-wheel sampling” in which each solution is assigned a fraction of a random variable’s range according to its fitness. For simplicity the random variable is typically chosen from the uniform distribution between 0 and 1.

A “roulette wheel” (Fig. 1d) is constructed by dividing each solution’s fitness by the sum of the fitness of all individuals. Specifically, the cumulative sum of the organisms’ fitness divided by the total fitness defines an allocation of the random variable range 0–1 to particular solutions (Fig. 1d). In this example, the sum of population fitness is 11 (Fig. 1c), and thus, organism A has a relative fitness of $4.5/11 = 0.41$, B a relative fitness of $3.5/11 = 0.32$, etc. In the roulette wheel organism D is thus assigned the sector from 0 to 0.045, organism C the sector from 0.045 to 0.27, organism B the sector from 0.27 to 0.59, and organism A the sector from 0.59 to 1. A solution (an organism) is selected for propagation if the random number instantiation generated is included in the organism’s sector (e.g., for organism A, if the random number generator produced a number between 0.59 and 1). The process is repeated for each organism in the new population.

Evolving Solutions

The basis for the new population generated by solution propagation is then subject to evolution before becoming the actual new population. Evolution in our example is represented by two operations – mutation and crossover. Mutation is simple – for each binary number in the genome, a probability is assigned to randomly flip the binary value at a particular location. Instantiations of the random numbers are then generated and the binary values changed accordingly (Fig. 1f). The crossover operation involves a few more steps. First, a random variable is used to pick whether crossover occurs for each solution. For a solution in which crossover is to occur, two parents need to be chosen. One parent is the one from which the solution was propagated, and the other can be

chosen randomly, for instance, by applying the roulette wheel again. Given the two parents, a random location on the genome is chosen to be the “crossover point” (Fig. 1g). Then a new organism is created by taking the genome from the first parent up until the crossover point, and the genome from the second parent from the crossover point to the end of the genome (Fig. 1g). Crossover will both trade multiple parameter values between solutions and also change the parameter value if the crossover point falls in the middle of a binary string encoding a particular parameter.

Evaluating Further Generations

At this point we have a new population with unknown fitness values, a state similar to the one just after initializing the population. In other words, we have completed the analysis of one generation. Accordingly, the genetic algorithm proceeds by iterating upon the above steps (fitness evaluation, propagation, etc.) for multiple generations. The number of generations to be evaluated can either be determined beforehand according to computational costs or generations can be iterated until a predefined success condition is achieved.

The genetic algorithm described above is just one possible implementation of the general concept (see, for instance, the journal *Evolutionary Computation* or the reference books (Goldberg 1989; Holland 1992; Mitchell 1996)). One important variant worth mentioning is the class of multi-objective optimization genetic algorithms in which the goal, like in many real-life problems, is to simultaneously optimize multiple, possibly conflicting measures of fitness (Deb 2001; see entry on ► “Multi-objective Evolutionary Algorithms”).

Theoretical Analysis of Genetic Algorithms

Beyond the empirical success of genetic algorithms as stochastic optimization approaches,

some theoretical results regarding their success can be derived. At a general level, the initial theory of genetic algorithm function, first formulated by J. Holland (1992), attributes the success of genetic algorithms to the ability to evaluate, discover, and improve building blocks of good solutions in an efficient, parallel fashion. To formalize the notion of building blocks, Holland introduced the concept of a schema. A schema is defined as a series of bits composed of three characters: 1, 0, or an *, where 0 and 1 correspond to their binary values and the asterisk corresponds to “either-1-or-0.” For instance, the schema 0**1 corresponds to all 4-bit strings that begin with a 0 and end with a 1 (e.g., 0111 or 0101).

The theoretical results concern the dynamics of the fraction of the population containing a particular schema. Specifically, whether schema associated with higher fitness values takes up larger parts of the population as the algorithm evolves through its iterations. Intuitively, this is a useful way to define whether the complex, stochastic dynamics of a genetic algorithm are indeed productive, since a good algorithm should promote good solutions. The mathematical results showing that schema tied to higher fitness indeed become more common in the population go beyond the scope of this entry but can be found in Holland’s textbook (Holland 1992).

Evolutionary Algorithms as a Tool for Understanding Natural Evolution

A less widely known application of evolutionary algorithms is theoretical analysis of simplified scenarios of natural evolution. Unlike the more generic nature of their use for optimization, genetic algorithms for analysis of evolution are quite study dependent. Therefore, we will only briefly introduce one such example (additional ones can be found in Holland 1992, Mitchell 1996).

Consider the puzzling phenomenon of the outlandish feathers of a peacock. Clearly, the feathers in and off themselves do not improve the animal's ability to survive and if anything actually impede it by higher expenditure of energy for their generation/maintenance and added difficulty in locomotion. Therefore, they may actually be detrimental to their survival, raising the question of how did such properties come about? Fisher (1958) originally suggested a qualitative solution – a “runaway process” by which a trait which initially improves survivability becomes exaggerated. The runaway nature of the process has to do with the fact that if members of a species preferentially choose partners according to some property (e.g., the elaborateness of plumage), not only will the animals with that property mate more, but their offspring are more likely to inherit the property itself (if of the sex that displays the property) or the preference for the property (if of the other sex). However, the question remains whether such a process would be stable, yielding long lasting populations that actually have such secondary traits.

This process was studied analytically by Kirkpatrick (1982) who was able to show that a whole range of steady-state equilibrium solutions exist whereby the frequency of organisms with secondary characteristics can range from either the entire population to no organisms at all (Kirkpatrick 1982). The intuition behind these solutions is that the dynamics become stable if the deficit that males suffer by having the secondary trait is offset by their mating advantage. Though it is satisfying to know that steady-state solutions with many organisms having secondary traits exist, one would like to know under which conditions the dynamics of the population develop to a state whereby secondary traits are a substantial part of the population, as we see in some species in nature. Moreover, one might be interested in examining the problem under more general assumptions than those required for the analytical solutions. Specifically, the analytical solution implicitly

assumes that each animal could mate with each other animal, an assumption that is clearly violated by the physical segregation of different animals.

To address these open questions, the study of this problem was extended by Collins and Jefferson (1992) who used genetic algorithms to simulate the evolution of individual organisms in a population of organisms. Simulating the dynamics has a number of favorable properties. First, in the simulation one can easily follow the detailed evolution of properties over time, allowing the full trajectory of the evolution of a trait in a population to be studied. In addition, more complicated assumptions, such as spatial segregation of populations, can be easily applied directly by adjusting the rules of the genetic algorithm. The simulations first confirmed that the steady-state solutions described by the analytical calculations can indeed be found when the original assumptions are used. Beyond that, the simulations showed that once the assumption regarding the ability of all animals to mate with all animals is lifted, the region of stability is found to be broader than that predicted by the analytical work. In addition, the validity of other assumptions (e.g., haploid instead of diploid organisms) was also explored, thereby advancing the understanding of sexual selection.

Summary

In summary, evolutionary algorithms, simulations of simplified models of natural evolution, are both scientific tools in their own right and general-purpose optimization approaches. Their study is an active, rich scientific field and the reader is encouraged to explore the relevant textbooks and reviews.

Definition

In 1948, Hodgkin distinguished between three classes of excitability on the basis of spiking patterns observed in crustacean axons. This classification scheme is still applied today because it captures fundamental differences in excitability that stem from how action potentials, or spikes, are generated. The nonlinear dynamical mechanism responsible for spike initiation in each cell class has been worked out, and the biophysical implementation of those dynamical mechanisms is reasonably well understood. Moreover, the differences in spike initiation that define each class confer differences in metrics like the phase-response curve (PRC) and spike-triggered average (STA), meaning that this simple classification scheme is predictive of important differences in neural coding.

Detailed Description

Historical Background

Based on single fiber recordings from the crab *Carcinus maenas*, Hodgkin (1948) identified three different classes of excitability. Class 1 axons were capable of spiking repetitively across a broad range of rates (5–150 spikes/s) in proportion to the stimulus intensity. Class 2 axons were also capable of spiking repetitively but across a narrower range (75–150 spikes/s),

Excitability: Types I, II, and III, Fig. 1 Defining differences in frequency-current (f - I) curves. Class 1 neurons can fire repetitively at arbitrarily slow rates, whereas class

2 neurons cannot, and class 3 neurons typically fire only a single spike even at high stimulus intensities

implying that they could not maintain slow repetitive spiking. Class 3 axons were by in large incapable of repetitive spiking and were also noted to spike at a shorter latency after stimulation than the other two classes. The differences that Hodgkin described can be readily distinguished from frequency-current (f - I) curves, as illustrated in Fig. 1: the f - I curve is continuous for class 1 neurons, discontinuous for class 2 neurons, and undefined for class 3 neurons.

Differences in Nonlinear Dynamics

Hodgkin's classification scheme has stood the test of time because it captures fundamental differences in neuronal excitability. The distinction between continuous and discontinuous f - I curves resurfaced most notably when, in 1989, Rinzel and Ermentrout provided dynamical explanations for the emergence of zero and nonzero frequency oscillations. Using a Morris-Lecar model, they showed that repetitive spiking in a class 1 neuron arises through a saddle node on invariant circle (SNIC) bifurcation, whereas repetitive spiking in a class 2 neuron arises through a subcritical Hopf bifurcation (Rinzel and Ermentrout 1989). These nonlinear dynamical mechanisms are illustrated in Fig. 2 and are summarized below. See also Izhikevich (2007) for an in-depth discussion.

The Morris-Lecar model they used comprises only two variables, a fast activation variable V and a slower recovery variable w . Behavior of the

model can thus be explained entirely on the basis of how those two variables interact. That interaction can be visualized by plotting V against w , as shown in Fig. 2a. How the variables evolve relative to one another is explained by how the V - and w -nullclines intersect, where nullclines represent everywhere in phase space where V or w remain constant. Importantly, depolarizing stimulation shifts the V -nullcline upward and can therefore change if and how that nullcline intersects the w -nullcline.

In class 1 excitability, the V - and w -nullclines intersect at three points prior to stimulation. The left intersection constitutes a stable fixed point that controls membrane potential. Stimulation shifts the V -nullcline upward. If it is shifted far enough (i.e., if stimulation exceeds current threshold or rheobase), two of the intersection points will be destroyed and repetitive spiking ensues – this constitutes an SNIC bifurcation. In effect, so long as the stable fixed point exists, membrane potential will stay at that point; but when that point is absent (which occurs during supra-threshold stimulation), the membrane potential enters a stable limit cycle that corresponds to repetitive spiking. Importantly, the trajectory around the limit cycle slows down each time it passes close to where the stable fixed point used to exist, which translates into a reduced rate of repetitive spiking. Indeed, at the precise stimulus intensity that causes the V -nullcline to shift just far enough that the left and center fixed points fuse, a homoclinic orbit is formed and firing rate is infinitesimally small.

Excitability: Types I, II, and III, Fig. 2 Differences in the nonlinear dynamical mechanisms responsible for spike initiation. (a) Phase planes show the fast activation variable V plotted against the slower recovery variable w . Bottom panels show enlarged views of mauve-shaded regions in top panels. Colored lines show V -nullclines (i.e., conditions for which $dV/dt = 0$) and gray lines show w -nullclines (i.e., conditions for which $dw/dt = 0$). Positions at which the V - and w -nullclines intersect represent fixed points and can be stable (s) or unstable (u) based on whether trajectories move toward or away from that point. On each phase plane, the V -nullcline is represented twice: once without stimulation (red) and once during excitatory stimulation (blue). Excitatory stimulation shifts the V -nullcline upward and can qualitatively change how it intersects the w -nullcline, as summarized in bifurcation diagrams in B. (b) Bifurcation diagrams show the fixed

points and limit cycles (represented by their maximum and minimum V) as stimulus intensity I_{stim} is systematically increased. In class 1 excitability, repetitive spiking begins when the stable fixed point and its neighboring unstable fixed point are destroyed through a saddle node on invariant circle (SNIC) bifurcation. In class 2 excitability, repetitive spiking begins when the stable fixed point is destabilized through a subcritical Hopf bifurcation. In class 3 excitability, a single spike is generated when abrupt stimulation shifts the V -nullcline enough that the start of the trajectory (which corresponds to the initial stable fixed point labeled with a red s) ends up below the shifted quasi-separatrix (shown as a dotted blue curve). A quasi-separatrix crossing can also generate single spikes in class 2 neurons for intermediate stimulus intensities. See text for details (Modified from Prescott et al. (2008))

In class 2 excitability, the V - and w -nullclines intersect at a single, stable point prior to stimulation. Spiking starts when the vertical shift in the V -nullcline caused by stimulation destabilizes that point – this constitutes a Hopf bifurcation. To a rough approximation, destabilization occurs when the V - and w -nullclines intersect to the right of the local minimum in the V -nullcline, whereas the fixed point is stable when the nullclines intersect

to the left of the minimum. Local stability analysis near the fixed point should be applied to determine stability more accurately.

These changes in nullcline geometry are directly reflected in the bifurcation diagrams shown in Fig. 2b. In bifurcation analysis, a parameter of interest (such as stimulus intensity) is systematically varied to determine at what values the system qualitatively changes behavior, e.g.,

switches from quiescence to repetitive spiking. The SNIC and Hopf bifurcations described above are labeled on those diagrams. Note that class 3 excitability is not associated with a bifurcation; the single fixed point remains stable throughout the entire range of tested stimulus intensities. However, upon an abrupt increase in stimulus intensity, a single spike can be produced, as shown by gray shading. The dynamical explanation for this spike initiation mechanism was worked out (Prescott et al. 2008) and is described below.

In class 3 excitability, the V - and w -nullclines intersect at a single stable point which, as already mentioned, remains stable even when stimulus intensity is very high. However, upon an abrupt increase in stimulus intensity, the V -nullcline moves instantaneously, whereas the system variables V and w lag behind. The system will move to the newly positioned stable fixed point, but can do so via different paths depending on where the trajectory starts relative to the quasi-separatrix – a boundary in phase space from which trajectories diverge. Trajectories starting below the quasi-separatrix make a long excursion around the elbow of the V -nullcline, resulting in a single spike, whereas those starting above the quasi-separatrix followed a direct, subthreshold route. Importantly, this mechanism requires that the stimulus intensity changes faster than the system variables V and w ; in geometrical terms, this means that stimulation can move the quasi-separatrix so that a point (V, w) that is above the quasi-separatrix before stimulus onset ends up below the quasi-separatrix after stimulus onset. Accordingly, this mechanism of spike initiation is referred to as a quasi-separatrix crossing because spike initiation requires that system variables cross from one side of the quasi-separatrix to the other.

Differences in Threshold Mechanism

Spike generation is essentially a two-dimensional phenomenon involving fast activation (positive feedback) to produce the rapid upstroke and slower recovery (negative feedback) to produce

the subsequent downstroke. The more important issue is to understand what happens at spike threshold. The three nonlinear dynamical mechanisms described above – the SNIC bifurcation, subcritical Hopf bifurcation, and quasi-separatrix crossing – provide that explanation, the implication being that Hodgkin's three classes of excitability reflect differences in threshold mechanism. The differences are most clearly revealed by considering local stability analysis near the fixed point in conjunction with the steady-state and instantaneous I - V curves, as illustrated in Fig. 3 and explained below.

- In class 1 excitability, $\partial I_{ss}/\partial V = 0$ at the saddle node (i.e., for just-threshold stimulation). This means that the steady-state I - V curve is non-monotonic with a local maximum above which depolarization activates net *inward* current at steady state; the negative feedback responsible for spike repolarization only begins to activate at suprathreshold potentials. Under these conditions, fast positive feedback has no slow negative feedback with which to compete at perithreshold potentials, and the voltage trajectory can, therefore, pass slowly through threshold. In fact, the net slow-activating current is inward at threshold, meaning that it cooperates (rather than competes) with fast-activating current to encourage spike initiation.
- In class 2 excitability, $-\frac{1}{C} \frac{\partial I_{inst}}{\partial V} > \frac{\phi_w}{\tau_w}$ at the unstable fixed point, meaning positive feedback (whose rate of activation is described by the left side of the inequality) outpaces negative feedback (whose rate of activation is described by the right side of the inequality) and repetitive spiking ensues. Unlike in class 1 excitability, the steady-state I - V curve is monotonic. This means that net slow-activating current is outward at threshold and competes (rather than cooperates) with fast-activating current to discourage spike initiation. Under these conditions, stimulation must not only force V high enough to activate fast-activating inward current, it must also do so fast enough that slower-activating outward current cannot catch up. It stands to reason that

Excitability: Types I, II, and III, Fig. 3 Biophysical basis for differences in spike initiation mechanism. *Top panels* show I - V curves for individual conductances comprising a modified Morris-Lecar model. *Bottom panels* show curves from *top panels* combined to give instantaneous and steady-state I - V curves. In class 1 excitability, the steady-state I - V curve has a local maximum (*arrowhead*), depolarization above which activates slow inward current. This slow positive feedback process acts cooperatively with activation of the fast sodium current, a fast positive feedback process. Under these conditions, spike initiation can occur arbitrarily slowly. In class 2 excitability, the steady-state I - V curve has no local maximum; instead,

depolarization above the local maximum of the instantaneous I - V curve causes increasing outward current. Under these conditions, slow negative feedback competes with fast positive feedback, meaning spike initiation must occur before slow negative feedback “catches up.” Class 3 excitability resembles class 2 excitability except that the outward current at perithreshold potentials is even stronger. In this example, voltage dependency of the slow conductance was varied (indicated by *red arrow* in *top panels*) to shift the model between different classes of excitability, but a multitude of other parameter changes can have equivalent effects that can be understood by the logic described above

spiking below a certain rate is disallowed since the voltage trajectory between spikes would be too slow to avoid strongly activating the slow outward current.

- In class 3 excitability, $-\frac{1}{C} \frac{\partial I_{\text{inst}}}{\partial V} < \frac{\phi_w}{\tau_w}$ at the stable fixed point. This means that at steady state, positive feedback activates too slowly to overcome negative feedback. Subthreshold activation of I_{slow} produces a steady-state I - V curve that is monotonic and sufficiently steep near the apex of the instantaneous I - V curve that V is prohibited from rising high enough to strongly activate fast inward current (I_{fast}). However, because the two feedback processes have different kinetics, a spike can be initiated if the system is perturbed from steady state: If V escapes high enough to activate I_{fast} (e.g., at the abrupt onset of stimulation), fast-activating inward current can overpower slow-activating

outward current – the latter is stronger when fully activated, but can only partially activate (because of its slow kinetics) before a spike is inevitable. In this way, a single spike is initiated before negative feedback forces the system back to its stable fixed point. Thus, like in class 2 excitability, slow-activating outward current competes with fast-activating inward current, but in class 3 excitability, the fast-activating current will only win that competition during stimulus transients. In other words, constant stimulation is never strong enough to sufficiently bias the competition in favor of fast-activating current, and constant stimulation thus never succeeds in driving repetitive spiking in class 3 neurons.

Interestingly, class 2 neurons exhibit a narrow stimulus range in which an abrupt increase in

stimulus intensity to a level that is insufficient to produce a Hopf bifurcation can nonetheless drive a single spike generated through a quasi-separatrix crossing (See Fig. 1). This has been demonstrated experimentally and implies that spike generation through two distinct mechanisms – a subcritical Hopf bifurcation and quasi-separatrix crossing – can occur in the same neuron based on different stimulus conditions. By comparison, the SNIC bifurcation cannot coexist with the other two spike initiation mechanisms. Nonetheless, a given neuron can shift between different classes of excitability (i.e., initiate spikes through different mechanisms) based on changes in its intrinsic membrane properties. In fact, different regions of the same neuron may generate spikes through different mechanisms based on subcellular variations in the densities of various ion channels.

To summarize, Hodgkin's three classes of excitability reflect differences in spike initiation dynamics. Fast-activating current is necessarily inward (depolarizing) at spike threshold. In class 1 excitability, net slow-activating current is also inward at perithreshold voltages and thus *cooperates* with fast-activating current during spike initiation. In class 2 and 3 excitabilities, net slow-activating current is outward (hyperpolarizing) at perithreshold voltages and thus *competes* with fast-activating current during spike initiation. Class 2 excitability exists if fast-activating inward current overpowers slow-activating outward current when constant stimulation exceeds threshold. Class 3 excitability exists if fast-activating inward current overpowers slow-activating outward current only during a stimulus transient, which precludes repetitive spiking during sustained stimulation.

Biophysical Basis

The fact that Hodgkin's three classes of excitability can be reproduced in a two-dimensional model demonstrates that nonlinear interaction between as few as two variables can account for the different threshold mechanisms that are the basis for each class. In other words, explaining the differences that Hodgkin described does not require complicated

models with dozens of different ion channels. That said, this does not mean that dozens of different ion channels are not contributing in one way or another to differences in excitability. Whereas currents with dissimilar kinetics interact nonlinearly, currents with similar kinetics sum linearly. Thus, net slow-activating current may, in a real neuron, comprise many different ion channels with similarly slow activation kinetics, and, likewise, net fast-activating current may comprise many different ion channels with similarly fast activation kinetics. The nonlinear interaction between the net-fast current and net-slow current could be qualitatively altered by alteration of any one of the contributing currents, meaning the class of excitability could be switched by any one of those changes. And of course ion channel inactivation is just as important as activation in determining the contribution of a given ion channel to net current. Furthermore, ultraslow processes like adaptation through slow activation of potassium currents or slow inactivation of sodium currents will modulate the fast-slow interaction; in other words, the ultraslow process can be approximated as a constant bias current over the time scale of a single fast-slow interaction (i.e., an individual spike), but that bias current will differ from one spike to the next. It stands to reason that spike initiation dynamics (ascertained in the two-dimensional subsystem) and the class of excitability that they convey will be dynamically modulated.

One point that should be stressed is that there is no unique ion channel or set of ion channels that is responsible for a given class of excitability. On the contrary, there are countless different ion channel combinations that can implement equivalent spike initiation mechanisms. In that respect, the biophysical basis for the spike initiation mechanism (and equivalently for Hodgkin's three classes of excitability) is highly degenerate. What is important is whether the fast and slow ion channels compete or cooperate during the spike initiation process.

Computational Consequences

The distinct dynamics associated with spike initiation in each of Hodgkin's three classes endows neurons with tuning to different stimulus features.

The cooperative spike initiation dynamics associated with class 1 excitability implements a low-pass filter. Spikes in class 1 neurons are thus preferentially elicited by constant or slowly fluctuating stimuli, and, as a result, those neurons tend to behave as good integrators. By comparison, the competitive spiking initiation dynamics associated with class 2 and 3 excitabilities implements a high-pass filter, although once combined with the low-pass filter implemented by membrane capacitance, the end result is band-pass filtering. Spikes in class 2 and 3 neurons are thus preferentially elicited by more rapidly fluctuating stimuli, and, as a result, those neurons tend to act as good coincidence detectors. Consistent with that description, class 1 neurons are primarily sensitive to stimulus intensity, whereas class 2 and 3 neurons are relatively more sensitive to the rate of change of stimulus intensity (Ratté et al. 2013).

Differences in tuning are directly reflected in measures such as the spike-triggered average stimulus (STA): class 1 neurons have broad, monophasic STAs, whereas class 2 and 3 neurons have biphasic STAs whose positive phase tends to be quite narrow. This is directly related to the shape of the phase-response curve (PRC), which is monophasic for class 1 neurons and biphasic for class 2 neurons (Ermentrout et al. 2007). Differences in the shape of the STA and PRC have a variety of interesting consequences (e.g., on synchronization), but that discussion exceeds the scope of the current chapter.

Summary

Hodgkin's classification of excitability is based on spiking patterns discerned over a range of stimulus intensities. This classification scheme is still widely used today, 65 years after it was initially proposed, because it captures fundamental differences in how neurons generate spikes. Spikes can arise through cooperation or competition between fast- and slow-activating currents. The biophysical basis for each spike initiation mechanism is degenerate insofar as many different ion channels contribute to the process and several different ion

channel combinations can produce equivalent excitability. What is most important is how those various ion channels interact during spike initiation. Different spike initiation mechanisms confer differences in tuning that are computationally important, thus further enhancing the utility of Hodgkin's classification scheme.

Extracellular Potentials, Forward Modeling of

Gaute T. Einevoll

Department of Mathematical Sciences and Technology, Norwegian University of Life Sciences, Ås, Norway

Department of Physics, University of Oslo, Oslo, Norway

Definition

Forward modeling of extracellular potentials refers to the calculation of electrical potentials recorded inside or outside the brain due to activity in neuronal (and, if relevant, glial) sources. This contrasts the “inverse” problem which amounts to estimating the underlying neural sources from recorded potentials.

Detailed Description

Extracellular potentials recorded inside or outside the brain are generated by transmembrane currents from cells in the vicinity of the recording electrode. To propagate from the membrane to a recording electrode inside the brain, the signal has to pass through brain tissue consisting of a tightly packed matrix of neurons and glial cells embedded in the extracellular medium (Nunez and Srinivasan 2006). A well-founded biophysical forward-modeling scheme based on volume-conductor theory (Rall and Shepherd 1968; Holt and Koch 1999), incorporating detailed reconstructed neuronal morphologies, allows for precise calculations of extracellular potentials – both *spikes* (the extracellular signatures of action potentials) and so-called *local field potentials* (LFPs). In *electroencephalographic* (EEG) recordings, the signal has to pass through neural tissue, dura matter, skull, and skin to reach the recording electrodes on the scalp, but the forward-modeling scheme has also been generalized to this situation.

Two-Step Forward Modeling Scheme

The modeling scheme naturally divides into two consecutive steps (Holt and Koch 1999):

1. First transmembrane currents from each neuron (and glial cells, if relevant) are calculated using multicompartmental modeling of simplified or biophysically detailed, morphological reconstructed neuron models (De Schutter 2009).
2. Next these transmembrane currents are used to calculate contributions to the extracellular potentials using a biophysical forward-modeling formula derived within so-called *volume-conductor theory* (Hämäläinen et al. 1993; Nunez and Srinivasan 2006).

Biophysical Forward-Modeling Formula

In volume-conductor theory the fundamental formula relating the contribution to an extracellular potential $\phi(t)$ recorded at position $\mathbf{r}$ from a transmembrane current $I_0(t)$ at position $\mathbf{r}_0$ is given by (Hämäläinen et al. 1993; Gratiy et al. 2017):

$$\phi(\mathbf{r}, t) = \frac{1}{4\pi\sigma} \frac{I_0(t)}{|\mathbf{r} - \mathbf{r}_0|}. \quad (1)$$

Here the brain tissue is assumed to be an infinite volume conductor, ϕ is set to be zero at a reference point infinitely far away, and σ is the *extracellular conductivity*.

This fundamental formula is derived assuming (Pettersen et al. 2012):

1. The *quasistatic approximation* of Maxwell's equations, i.e., omitting the terms with time derivatives of the electric ($\mathbf{E}$) or magnetic fields ($\mathbf{B}$).
2. A *linear* extracellular medium, i.e., $\mathbf{j} = \sigma\mathbf{E}$, where $\mathbf{j}$ is the current density, $\mathbf{E}$ the electrical field, and σ a (scalar) proportionality constant. It is further assumed that the electrical medium is
 - (a) Ohmic, i.e., no capacitive effects so that σ is independent of frequency (corresponding to a real-valued σ , that is, no imaginary component (Grimnes and Martinsen 2015),
 - (b) *Isotropic* (same in all directions), and

- (c) *Homogeneous* (same everywhere).
3. No contribution to the extracellular potential from ion *diffusion*.
 4. No contribution to the extracellular potential from *advection*, that is, ions moving by flow of the liquid in which they are suspended.

Assumption 1 seems well fulfilled for the frequencies inherent in neural activity, i.e., less than a few 1000 Hz (Hümäläinen et al. 1993; Nunez and Srinivasan 2006).

Assumption 2a has been questioned (Bédard et al. 2004), but on balance recent experiments point to a largely frequency-independent medium (Logothetis et al. 2007; Wagner et al. 2014; Miceli et al. 2017). Also, a frequency-dependent conductivity can be incorporated in the forward-modeling scheme by considering each frequency (Fourier) component separately, see Miceli et al. (2017) for an example. Assumption 2b is not always fulfilled, but the forward-model formula in Eq. (2) can be generalized to account for, for example, different conductivities in different directions (Nicholson and Freeman 1975; Logothetis et al. 2007; Ness et al. 2015). Likewise, assumption 2c is not always fulfilled, for example at interfaces between gray matter and the cortical surface where there is a discontinuity in electrical conductivity. However, the forward-model formula can be generalized to account for such discontinuities by means of the *Method of Images (MoI)* from electrostatics (Nicholson and Llinas 1971; Pettersen et al. 2006). MoI has also been used to model electrical potentials in multi-electrode arrays (MEAs) where cortical slices covered by highly conducting saline are placed on insulating chip surfaces (Ness et al. 2015; Miceli et al. 2017). Further, when the extracellular conductivities around the recording electrodes have such a complicated spatial structure that analytical forward-model formulas either do not exist or are unpractical, one can always solve the forward problem by means of *finite element modeling* (FEM) (McIntyre and Grill 2001; Mechler and Victor 2012; Lempka and McIntyre 2013; Ness et al. 2015; Miceli et al. 2017).

Assumption 3 is not always fulfilled, and if so other computational schemes must be considered (Haldnes et al. 2016), see section “[Limitations and](#)

[Generalizations](#)” below. Assumption 4 is generally expected to be fulfilled, however, as liquid flow in extracellular brain tissue is slow (Gratny et al. 2017) and the extracellular solutions essentially electroneutral.

The above forward-model formula applies to the situation with a single transmembrane current I_0 , but since electromagnetic theory is linear, contributions from several transmembrane current sources simply add up. In multicompartmental modeling where the neuron is divided into N compartments, the formula straightforwardly generalizes to

$$\phi(\mathbf{r}, t) = \frac{1}{4\pi\sigma} \sum_{n=1}^N \frac{I_n(t)}{|\mathbf{r} - \mathbf{r}_n|}, \quad (2)$$

where $I_n(t)$ is the transmembrane current (including the capacitive membrane current) in compartment n , and $\mathbf{r}_n$ is the “mean” position of the compartment, e.g., at the center of a spherical soma compartment or the mid-point of a cylindrical dendritic compartment. This scheme corresponds to the so-called *point-source* approximation (Holt and Koch 1999; Pettersen et al. 2008) since all transmembrane currents into the extracellular medium from each compartment n go through a single point. Another scheme, the more commonly used *line-source* approximation, assumes the transmembrane currents from each cylindrical compartment to be evenly distributed along a line corresponding to the cylinder axis (Holt and Koch 1999).

The above forward-modeling formulas predict potentials at point electrodes’, while real recording electrodes of course have finite physical extensions. Finite-sized electrodes appear to measure the average potential across the uninsulated electrode surface (Nelson and Pouget 2010), and a natural approximation is thus to approximate the measured potentials by the average of the computed potentials across the electrode’s surface (Lindén et al. 2014; Ness et al. 2015).

Applications

Different frequency bands of the recorded extracellular potentials contain different types of information about the underlying neural activity. The

high-frequency part of the signal ($> \sim 500$ Hz), the *multi-unit activity* (MUA), contains information about the firing of action potentials (Buzsáki 2004; Gold et al. 2006; Pettersen and Einevoll 2008), while information about how the neuron integrates synaptic inputs appears primarily contained in the low-frequency part ($< \sim 500$ Hz), i.e., the *local field potential* (LFP). The forward-modeling scheme has been used, with detailed reconstructed neuronal morphologies, to calculate both somatic spikes (i.e., extracellular signatures of action potentials) (Holt and Koch 1999; Gold et al. 2006, 2007; Pettersen et al. 2008; Pettersen and Einevoll 2008; Thorbergsson et al. 2012; Schomburg et al. 2012; Camuñas-Mesa and Quiñero 2013; Hagen et al. 2015), spikes in axonal projections (McColgan et al. 2017; Kuokkanen et al. 2018), and LFPs (Pettersen et al. 2008; Lindén et al. 2010, 2011; Schomburg et al. 2012; Leski et al. 2013; Reimann et al. 2013; Mazzoni et al. 2015; Tomsett et al. 2015; Ness et al. 2016, 2018; Hagen et al. 2016, 2017; Parasuram et al. 2016) generated by individual or populations of neurons.

Local field potentials recorded in cortex stem from populations of neurons, and detailed theoretical analysis based on the forward-modeling scheme has revealed that the level of *correlations* in synaptic inputs to the neurons surrounding the recording electrode is critical for determining the amplitudes of the recorded potentials (Lindén et al. 2011; Leski et al. 2013; Ness et al. 2018). Correlated synaptic inputs may, depending on the spatial distribution of synapses onto the neurons, substantially boost the amplitude compared to the same situation with uncorrelated inputs (Lindén et al. 2011). Further, the boosting effect is particularly prominent for low frequencies (Leski et al. 2013; Ness et al. 2018).

Charge conservation implies that $\sum_{n=1}^N I_n(t)$ in Eq. (2) is zero at all times, so that a point-neuron model (where $N = 1$) does not generate an extracellular potential (Pettersen et al. 2012). A hybrid scheme for computing LFPs from point-neuron models has thus been developed. Here the spiking dynamics is computed in point-neuron networks, while the LFP is computed in a second step using multicompartmental neuron models (Hagen et al. 2016). Further, a simplified formula for

computing LFPs generated by two-population networks of integrate-and-fire neurons has been derived (Mazzoni et al. 2015).

For the electrical potential recorded by an EEG electrode at the scalp, the forward model in Eq. (2) assuming a homogeneous electrical medium is no longer applicable due to different electrical conductivities of neural tissue, cerebrospinal fluid (CSF), skull, and scalp. However, a forward-modeling scheme can still be constructed, either by means of analytical expressions from assuming, for example, a four-sphere head model (Nunez and Srinivasan 2006; Næss et al. 2017; Hagen et al. 2018) or by numerical solutions using realistic volume conductor models (Bangera et al. 2010; Vorwerk et al. 2014). Likewise, *electrocorticographical* (ECoG) signals, that is, signals recorded with electrodes placed at the cortical surface, can be modelled either by use of MoI or by spherically symmetric head models (Hagen et al. 2018).

For further reading, see reviews in Pettersen et al. (2012) and Einevoll et al. (2013a, b).

Limitations and Generalizations

Even if spatially varying, anisotropic, and frequency-dependent electrical conductivities can be incorporated, the forward-model scheme within volume-conductor theory has several inherent limitations. For one, the scheme is not self-consistent as the extracellular potential generated by transmembrane currents change the membrane potential and thus feeds back on the neural dynamics. This feedback effect is known as *ephaptic coupling* (Holt and Koch 1999), and proper inclusion of it requires computational extensive schemes (Agudelo-Toro and Neef 2013; Tveito et al. 2017) (but see Goldwyn and Rinzel 2016). However, since the extracellular potentials typically are much smaller than a millivolt, while the membrane potentials are many tens of millivolts, this effect can in many cases be expected to be small.

Another limitation is the absence of diffusion effects: Even in the absence of transmembrane currents, spatial gradients of ion concentrations may by itself set up extracellular potentials. These can be modelled by the Kirchhoff-Nernst-Planck (KNP) scheme (Halnes et al. 2016;

Solbrå et al. 2018), or the Poisson-Nernst-Planck (PNP) scheme (Lopreore et al. 2008; Pods et al. 2013), where both extracellular potentials and ion concentrations are explicitly modeled.

Extracellular Signal-Regulated Kinases, Models of

Susana R. Neves

Department of Pharmacology and Systems Therapeutics, Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA

Synonyms

ERK1, 2; MAPK1, 2; p42/p44 MAPK

Definition

Mitogen-activated protein (MAP) kinases consist of a family of protein kinases activated by a variety of cellular stimuli (Pearson et al. 2001). Four subfamilies of mammalian MAPK have been identified: ERK1 and ERK2: JNK; p38; and ERK5. Extracellular regulated kinase 1 and 2 (ERK1, ERK2), the original MAPK, was discovered as a kinase activity regulated by insulin. For a historical perspective on the discovery of the ERK cascade, see Blenis (1993). ERK1 and ERK2 (also known as p44 and p42 MAPK) signaling is key for the induction of synaptic plasticity and is essential for learning and memory (Thomas and Huganir 2004).

Detailed Description

The core ERK signaling module consists of a three-tiered kinase cascade: the MAPKKK Raf1 or B-Raf that phosphorylates and activates the MAPKK MEK1/2 that in turn phosphorylates and activates the MAPK ERK1/2. The small G protein Ras activates Raf, the first kinase in the cascade. Activation of guanyl-nucleotide exchange factors (GEFs) facilitates the exchange of GDP for GTP in Ras, leading to its activation. GTPase-activating proteins (GAPs) counteract this activation by enhancing the hydrolysis of GTP to GDP catalyzed by Ras itself. Ras–GTP binds to Raf, promoting its membrane association and inducing a conformational change that results in the activation of Raf. Active Raf in turn phosphorylates and activates the second kinase in the cascade MAPK/ERK kinase (MEK). MEK's only known substrate is ERK, the third kinase in the cascade. ERK is a serine/threonine kinase with a number of cytoplasmic and nuclear substrates. In the cytoplasm, active ERK phosphorylates ionic channels such as Kv4.2, other kinases such as ribosomal protein S6 kinases (RSKs), and enzymes such as phospholipase A2 (PLA2), involved in the synthesis of arachidonic acid (AA) and the phosphodiesterase PDE4, an enzyme that degrades cAMP. Nuclear targets include transcription factors such as CREB, and other kinases such as RSK-related mitogen- and stress-activated kinases (MSKs) (Reviewed by Yoon and Seger 2006).

ERK Activation in Neurons

Many of the extracellular ligands that play crucial roles in synaptic plasticity, such as growth factors, hormones, and modulatory neurotransmitters, also activate ERK. These ERK-activating ligands act through several distinct classes of cell surface receptors, such as receptor tyrosine kinases (RTKs), G protein-coupled receptors (GPCRs), or ligand-gated ion channels. Growth factor

activation of ERK starts with the ligand-mediated tyrosine autophosphorylation of the RTK (e.g., brain-derived neurotrophic factor (BDNF) receptor TrkB) and results in the formation of a membrane-associated complex of adapter proteins that promote Ras activation via the Ras–GEF SOS.

ERK is also activated by a number of neurotransmitter receptors such as the G_q -coupled muscarinic acetylcholine receptors (mAChRs) and metabotropic glutamate receptors (mGluRs), or the G_s -coupled β -adrenergic receptor (β -AR). Activation of ERK by GPCRs coupling to heterotrimeric G proteins, G_q , G_i , and G_s , occurs by distinct mechanisms (Hawes et al. 1995; Williams et al. 1998). G_i and G_q can activate ERK via their $\beta\gamma$ subunits, while G_s activates ERK by a cAMP-dependent mechanism. For example, B-Raf can be activated by the small G protein Rap1 in response to increases in cAMP, resulting in ERK activation (Emery et al. 2013). In neurons, ERK activation also occurs through elevation of intracellular calcium, due to membrane depolarization or release from intracellular stores. For instance, glutamate opening of *N*-methyl-d-aspartate (NMDA)-type channels lead to an influx of calcium into the neuron resulting in ERK activation. Several mechanisms for calcium activation of ERK exist, including activation of calcium-sensitive Ras–GEFs, transactivation of RTKs, and activation of kinases such as PYK or PKC (Cullen and Lockyer 2002).

Computational Models of ERK Signaling in Neurons

Numerous computational models of ERK signaling have been published, exploring the different facets of this versatile signaling cascade. The ERK signaling cascade three-tiered topology and feedback regulation impart it with context-specific properties, such as ultrasensitivity, bistability, and oscillations (Ferrell Jr and Machleder 1998; Kholodenko 2000). Spatial

models of ERK have predicted an enhancement of dendritic ERK activation in response to β AR stimulation (Neves et al. 2008).

In neurons, particular attention has been given to the role of ERK interfacing with calcium signaling during synaptic plasticity. Bhalla and Iyengar (1999) developed one of the initial models of ERK in neurons, examining the possible storage of information within signaling networks underlying long-term potentiation. In this compartmental model of a CA1 hippocampal neuron, the authors explored the contribution of ERK to the maintenance of CaMKII activation after a glutamate stimulus was terminated. The model proposed the feedback loop consisting of ERK-activating PLA2, leading to increase in arachidonic acid (AA) and PKC activation. PKC can then sustain ERK active through regulation of Ras and MEK1 and MEK2. This feedback loop can give rise to bistability, as it amplifies the initial ERK activation into a sustained signal. The feedback loop involving ERK–PLA2–AA–PKC can also enhance PKA activation (as explained in the next paragraph) and thus decrease the activity of PP1, the phosphatase acting on CaMKII, promoting the phosphorylation of AMPAR. A follow-up study by Kuroda et al. (2001) developed a model of cerebellar long-term depression and included the same feedback loop involving ERK–PLA2–AA–PKC, and in this context, sustained PKC activation led to the phosphorylation and internalization of AMPAR. Other studies with similar feedback mechanisms have been further developed to include additional molecules, such as PKMzeta (Ajay and Bhalla 2004, 2007). Recently, a model of ERK regulation of PDE4 has highlighted one of the mechanism by which ERK controls AMPAR trafficking (Song et al. 2013).

ERK can also regulate synaptic plasticity by enhancing the actions of PKA. In *Aplysia*, the molecular process that enables the association of a sensory cue with a withdrawal reflex is called long-term facilitation (LTF) and is dependent on the neurotransmitter serotonin (5-HT).

5-HT activates PKA and ERK, and these two kinases regulate transcription essential for LTF by phosphorylating and activating CREB. An ERK model was developed that explored the signaling mechanism underlying LTF (Pettigrew et al. 2005). In this model, ERK modulation of PKA activity led to the coincident activation of CREB within a restricted time window. ERK was proposed to prolong PKA activation by increasing the translation of the regulatory subunit of PKA. ERK could also enhance PKA activation of CREB1 by phosphorylating CREB2, reducing its repressor activity on CREB1.

Byrne and colleagues further modified their original ERK model by abstracting the combined output of PKA and ERK pathways into a species called “inducer” (Zhang et al. 2012). The goal of this study was to use the computational model of ERK and PKA signaling to find training protocols to improve learning in *Aplysia*. They searched for 5-HT patterns of stimulation that would give rise to the most effective synergy of ERK and PKA activation and thus the highest accumulation of “inducer” and CREB activation. The identified protocol was then tested in experimental behavioral assays and shown to be significantly superior to standard protocols of learning in *Aplysia*.

Definition

In response to acoustic inputs (sounds), neural activity generates extracellular voltages throughout the auditory pathway. Sound-evoked extracellular voltages in the auditory brainstem – termed the *neurophonic* – exhibit distinctive temporal and spatial patterns. Computational modeling demonstrates how neural activity in an auditory brainstem region known as the medial superior olive (MSO) can produce these extracellular voltages.

Detailed Description

Extracellular Voltage Recordings in the Auditory Brainstem

An important center of auditory processing in the auditory pathway is the medial superior olive (MSO). In this nucleus, neurons receive inputs that originate from both ears. Spiking activity of MSO neurons is sensitive to the relative timing of synaptic inputs, which allows these neurons to convey information about interaural time differences, an important cue for sound source location (Grothe et al. 2010).

In addition to evoking spiking activity in MSO neurons, sounds also cause extracellular voltages (V_e) in the brainstem. Since extracellular voltages in the brain are generated by electric currents that flow through neurons and their synapses (Einevoll et al. 2013) and since sound-evoked extracellular voltages are observed in and around the MSO, it has long been hypothesized that MSO neurons are a dominant generator of these extracellular voltages. These signals – known as the *neurophonic* – can have distinctive temporal and spatial features. In response to sinusoidal acoustic input stimuli (pure tones), the neurophonic is periodic with fundamental frequency that matches the input tone. The spatial pattern of these responses resembles voltages generated by a dipole distribution of current (Galambos et al. 1959; Biedenbach and Freeman 1964; Tsuchitani and Boudreau 1964; Mc Laughlin et al. 2010). In the auditory brainstem of cats, tone-evoked V_e signals are largest for frequencies between 500 and 2000 Hz (Mc Laughlin et al. 2010) and can be observed in response to frequencies as high as 4000 Hz (Boudreau 1965).

Computational Models of Extracellular Voltages in the MSO

Standard models of neural activity describe the dynamics of membrane potential – the voltage difference across the cell membrane – but do not explicitly calculate the voltage outside the cell. Since extracellular voltage is the result of current flow outside of the cell, computational models of neurally generated V_e must track currents and voltages both inside and outside the cell. In principle, then, models of extracellular voltages must describe current flow throughout the brain which acts as a three-dimensional volume conductor. Models of the neurophonic have successfully simplified this problem by noting spatial symmetry in the arrangement of MSO neurons and temporal structure of inputs to MSO neurons. MSO neurons are relatively well-aligned in space with dendrites that extend, roughly, parallel to one another (Rautenberg et al. 2009). In addition, like most regions of the auditory pathway, there is a tonotopic organization in the MSO with nearby neurons tuned to similar frequencies. As a result of this orderly arrangement of MSO neurons and their synaptic inputs, it is convenient and

plausible to assume that local subpopulations of MSO neurons are nearly identical and arranged symmetrically and that nearby neurons in local subpopulation receive synaptic inputs that arrive in synchrony. In this idealized scenario, voltage inside an MSO neuron (V_i) and voltage outside (V_e) can be calculated simultaneously in coupled, one-dimensional spatial domains. The region surrounding a neuron has been termed the *virtual cylinder* of extracellular space in Goldwyn et al. (2014). These intracellular and extracellular spaces are coupled by transmembrane currents; see the schematic in Fig. 1. The use of symmetry and synchrony arguments was pioneered by Rall and Shepherd (1968) for modeling V_e in the olfactory bulb.

The anatomy and biophysics of neurons shape extracellular voltage responses. Models of MSO-generated V_e have included important biophysical details such as voltage-gated ion currents and bipolar morphology (dendrites extending away from a central soma region) (Goldwyn et al. 2014). Since spikes are small and difficult to detect in extracellular recordings in the region of the MSO, spike-generating sodium current is not thought to contribute appreciably to V_e .

The Dipole Model of MSO-Generated Extracellular Voltages

The elongated shape of MSO neurons – two dendrites, extending away from a central soma – causes MSO neurons to generate V_e in a manner similar, qualitatively, to a current dipole. A sound played to one ear evokes neural activity in the auditory nerve that is transmitted along the auditory pathway. These responses cause excitatory synaptic currents to enter as inward flows of positive ions into the dendrites on one side of a local subpopulation of MSO cells. This creates a current *sink* and a negative deflection of V_e near the sites of synapses. The principle of conservation of current requires that this inward flow be balanced, in each cell, by an outward flow of current. Consequently, the soma and dendrites on the opposite side of the MSO act as current *sources* and create positive deflection of V_e . In short, in response to sounds played to one ear, MSO neurons act similar to current dipoles. Indeed, dipole-like V_e patterns are observed in vivo (Biedenbach and

Extracellular Voltage Recordings in the Medial Superior Olive, Modeling of, Fig. 1 Computational modeling of extracellular V_e in MSO. (a) MSO neurons are aligned in space with dendrites that extend away from cell bodies and are parallel, roughly. (b) An idealized local subpopulation of MSO neurons represented as identical cells with bipolar dendrites and spatially symmetric arrangement. Blue regions represent extracellular regions surrounding each cell. (c) Schematic of a portion of an MSO neuron, represented in a computational model as a

collection of compartments. Current inside the cell (red) determines the intracellular voltage (V_i). Current outside the cell (blue) creates extracellular voltage V_e . Assumptions of spatial symmetry of MSO neurons and temporal synchrony of neural activity in a local subpopulation allow intracellular and extracellular regions to be idealized as one-dimensional domains coupled by the flow of transmembrane current (green). (Figure reproduced from Goldwyn et al. (2014) with permission of the Society for Neuroscience)

E

Extracellular Voltage Recordings in the Medial Superior Olive, Modeling of, Fig. 2 Simulations of MSO neuron model produce dipole-like V_e in response to 1000 Hz excitatory synaptic inputs on one dendrite. (a) Simulated membrane potential V_m . (b) Simulated extracellular voltage V_e . Note the change in spatial dimension (vertical axis) compared to (a), with the black bar indicating the location of the modeled MSO neuron. (c) Comparison of synaptic current flow (black) and net

transmembrane current flows on portions of the cell. The soma and distal dendrite are current sources (net current is positive, outward). The dendrite proximal to the synaptic input is a current sink (net current is negative, inward). Thus the MSO neuron model acts, roughly, as a current dipole in response to dendrite-targeting excitation. (Figure adapted from Goldwyn et al. (2014) with permission of the Society for Neuroscience)

Freeman 1964; Mc Laughlin et al. 2010). These spatial patterns can be reproduced in models that treat MSO neurons as current dipoles (Mc Laughlin et al. 2010) and in biophysically based models of MSO neurons (Goldwyn et al. 2014, 2017); see Fig. 2.

Signatures of Synaptic Inhibition in Non-dipole-Like Extracellular Voltages

Not all V_e responses are well-described by a dipole model. MSO neurons also receive soma-targeting inhibition, and computational modeling that

includes this additional current source can account for non-dipole features in V_e responses (Goldwyn et al. 2017). Combinations of soma-targeting inhibition and dendrite-targeting excitation reproduce, quantitatively, diverse and frequency-dependent neurophonic responses to pure tone stimuli, as shown in Fig. 3.

Significance of Extracellular Voltage in the MSO

The MSO is one of the first stages in the auditory pathway that combines inputs from both ears.

Extracellular Voltage Recordings in the Medial Superior Olive, Modeling of, Fig. 3 Non-dipole features of the neurophonic accounted for in a MSO model with excitation and inhibition. Recorded and simulated V_e patterns are presented in pairs. Responses are to pure tones at three frequencies. From left to right, 600, 1200, and 1800 Hz pure tones. In experiments, tones are played to one ear (monaural); see Mc Laughlin et al. (2010) for details. In simulations synaptic inputs target two sites on the neuron: off-center (representing dendrite-targeting

excitation) and the center of the neuron (representing soma-targeting inhibition). Each panel displays cycle-averaged spatial-temporal patterns of V_e , with the period of averaging defined by the input tone. Black vertical bars in the *model* panels represent the location of the model neuron. Responses to the 1200 Hz tone are mostly “dipole-like.” Responses to 600 and 1800 Hz tones have non-dipole features. (Figure adapted from Goldwyn et al. (2017) with permission of the Society for Neuroscience)

MSO neurons play an important role, therefore, in sound localization and other aspects of binaural (“two-eared”) hearing. There are technical challenges in intracellular recording individual MSO neurons *in vivo*, although there have been recent successes (Franken et al. 2015). Recording extracellular voltages in the auditory brainstem is, therefore, a useful alternative approach to study the function of MSO neurons. Computational modeling and model-based analysis of these V_e signals provide insights into MSO activity based on this accessible source of *in vivo* data.

Computational modeling of V_e can also reveal new principles of neural activity. Extracellular voltages in the MSO can be several millivolts in amplitude. This raises a question: do MSO neurons interact via this large-amplitude, endogenously generated extracellular voltage? This type of non-synaptic neural interaction has been termed *ephaptic coupling*. Simulations of MSO neurons coupled via their endogenously generated V_e demonstrate that the neurophonic could, in principle, alter spiking activity of MSO neurons (Goldwyn and Rinzel 2016).

Synonyms

[Associative learning](#); [Eyelid conditioning](#); [Motor learning](#)

Definition

Eye-blink conditioning is both a procedure and a type of learning. The delay procedure includes the repeated presentation of a conditioned stimulus (CS) that does not elicit eyelid closure before training followed shortly (150–2000 ms) by an unconditioned stimulus (US) that elicits an eyelid closure unconditioned response (UR) before training. After repeated paired presentations of the CS and US, the organism will develop an eyelid closure conditioned response

Unconditioned Response

Conditioned Response

Eye-Blink Conditioning, Fig. 1 Diagram of eye-blink conditioning procedure and timing of the conditioned response. At the start of training, an unconditioned response (eyelid closure) occurs after the onset of the unconditioned stimulus (US). With repeated presentations of the conditioned stimulus (CS) and the US, a conditioned eyelid closure starts before the onset of the US

(CR) which precedes the onset of the US (Fig. 1). Unpaired presentations of the CS and US do not result in the development of a CR. Eye-blink conditioning therefore establishes associative learning based upon the predictive relationship between the CS and US – the CS predicts that the US is coming. It also establishes learned timing such that maximum eyelid closure for the CR is timed to the onset of the US in well-trained subjects. Eye-blink conditioning has been studied in humans, cats, dogs, ferrets, frogs, mice, monkeys, rabbits, rats, sheep, and turtles.

Detailed Description

Essential Role of the Cerebellum in Eye-Blink Conditioning

Eye-blink conditioning depends on the intermediate cerebellum ipsilateral to the trained eye (McCormick and Thompson 1984). Lesions of the ipsilateral anterior interpositus nucleus block acquisition of eye-blink conditioning, even after

thousands of training trials, and completely abolish CRs acquired before the lesion. Reversible inactivation of the anterior interpositus nucleus and overlying cortex also blocks acquisition of the CR. When the reversible inactivation is ended, the rate of acquisition is the same as in animals that were not previously trained, indicating that there was no memory trace established during training (i.e., no savings) with cerebellar inactivation (Krupa et al. 1993). Cerebellar inactivation administered after the training sessions impairs eye-blink conditioning, indicating that memory consolidation is disrupted by post-training inactivation (Attwell et al. 2002). The findings of the lesion and reversible inactivation studies suggest that the memory underlying eye-blink conditioning is stored within the cerebellum (Freeman and Steinmetz 2011).

Convergence of CS and US Sensory Pathways in the Cerebellum

The neural pathways that convey CS sensory input to the cerebellum have been determined for auditory and visual stimuli (Freeman and Steinmetz 2011). The auditory CS pathway includes the lower brainstem auditory nuclei and the medial auditory thalamus (Fig. 2). The medial auditory thalamus then projects to the lateral pontine nucleus which sends its mossy fiber projection to the cerebellar cortex and nuclei. Mossy fibers synapse with granule cells in the cerebellar cortex which then send their parallel fiber projection to Purkinje cells and inhibitory interneurons. The visual CS pathway includes retina projections to the nucleus of the optic tract and the ventral lateral geniculate and projections of these nuclei to the medial pontine nuclei. The US pathway includes projections from the trigeminal nucleus

Eye-Blink Conditioning, Fig. 2 A simplified schematic diagram of the neural circuitry underlying delay eye-blink conditioning. The cerebellar anterior interpositus nucleus (AIN) and Purkinje cells (Pc) in the cerebellar cortex receive convergent input from the conditioned stimulus (CS, green) and unconditioned stimulus (US, red) neural pathways. The CS pathway for an auditory CS includes the cochlear nuclei (CN), superior olive (not shown), lateral lemniscus (not shown), inferior colliculus (IC), medial auditory thalamus (MAT), basilar pontine nuclei (PN), mossy fiber (mf) projection to the AIN and cortical granule cells (Gc), and the parallel fiber (pf) projections to Purkinje

cells. The US pathway includes the trigeminal nucleus (TN), dorsal accessory division of the inferior olive (IO), and the climbing fiber (cf) projection to the AIN and Pc. The output pathway for performance of the conditioned blink response (orange) includes the AIN projection to the red nucleus (RN) and its projection to facial motor nucleus (FN) which causes the eyelid closure conditioned response (CR). Feedback projections from the AIN to the PN, MAT, and IO regulate CS and US input to facilitate acquisition and maintain plasticity within the cerebellum. Inhibitory synapses are depicted by a flat ending. All other synapses are excitatory

to the inferior olive; the inferior olive sends its climbing fiber projection to the cerebellar cortex and nuclei (Fig. 2). The CS pathway receives positive feedback from the cerebellum to the pontine nuclei and thalamus, whereas the US pathway receives an inhibitory feedback projection from the cerebellum to the inferior olive (Fig. 2).

Cerebellar Mechanisms of Associative Learning

Computational models of cerebellar learning posit that the concurrent activation of the mossy fiber pathway and climbing fiber pathway during CS-US training trials induces synaptic plasticity. Some of the original and most influential models posited synaptic plasticity at parallel fiber-to-Purkinje cell synapses (Albus 1971; Marr 1969). More recent models posit synaptic plasticity in mossy fiber-to-interpositus nucleus synapses as well as parallel fiber-to-Purkinje cell plasticity (Li et al. 2013). Purkinje cell projections to the cerebellar nuclei are inhibitory which have led models to include synaptic depression at parallel fiber synapses with Purkinje cells. The synaptic depression produces pauses in Purkinje cell activity during the CS, which then reduces tonic inhibition of the interpositus nucleus. This release from inhibition combined with synaptic enhancement at mossy fiber-to-interpositus nucleus synapses drives an increase in interpositus nucleus activity that in turn drives premotor neurons in the red nucleus to activate the facial motor nucleus to produce the CR.

Empirical evidence supporting the models of cerebellar learning comes from neurophysiological studies. Purkinje cells show pauses in simple spike activity in vivo that develop during eye-blink conditioning (Jirenhed et al. 2007). These pauses in Purkinje cell activity are thought to be the result of synaptic depression. Neurons in the anterior interpositus nucleus show increases in activity that develop during training (McCormick and Thompson 1984), which are thought to be the result of release from Purkinje cell inhibition and synaptic enhancement. These increases in activity parallel the amplitude and time course of the CR both across training trials and within training trials (Halverson et al. 2010).

Summary

Eye-blink conditioning is a type of associative motor learning that depends on the cerebellum. Sensory inputs from the CS and US converge on neurons within the cerebellar cortex and nuclei. Paired presentations of the CS and US during eye-blink conditioning cause induction of synaptic depression between parallel fibers and Purkinje cells and synaptic enhancement between mossy fibers and anterior interpositus nucleus neurons. The synaptic plasticity within the cerebellar cortex and nuclei is the mechanisms underlying memory storage within the cerebellum.

Definition

Facilitation is a temporary increase in postsynaptic response to a presynaptic action potential or depolarization induced by a preceding presynaptic depolarization. It is distinguished from longer-term components of activity-dependent synaptic enhancement by its low activation threshold (a pair of action potentials is often sufficient, hence the term *paired-pulse* facilitation) and short persistence time: in most cases, facilitated response decays back to initial amplitude within less than a second after the stimulus train. Facilitation is very common in central and peripheral synapses of both vertebrate and invertebrate nervous systems; it is readily observed under conditions of low initial vesicle release probability, but is often occluded by synaptic depression when the initial vesicle release probability is sufficiently high. Biophysical models of facilitation go beyond a simple phenomenological description and often combine a model for presynaptic Ca^{2+} dynamics with a model of Ca^{2+} binding to exocytosis sites that trigger vesicle fusion.

Detailed Description

While postsynaptic effects can contribute to short-term enhancement of synaptic response, in most synapses facilitation is caused by some action of presynaptic Ca^{2+} ions entering during stimulation, which is intuitive in view of the steep nonlinear

dependence of baseline exocytosis rate on Ca^{2+} concentration ($[\text{Ca}^{2+}]$). However, simple whole-terminal accumulation of free Ca^{2+} at best provides a partial contribution to facilitation, since such residual Ca^{2+} elevation is expected to be small compared to the high concentration of Ca^{2+} near an open Ca^{2+} channel, believed to be essential for triggering exocytosis (so-called Ca^{2+} nano- or microdomain); considerable global Ca^{2+} accumulation is also inconsistent with the brief (“phasic”) nature of synaptic response. Several alternative models for facilitation have been proposed and are categorized below in terms of the respective physiological mechanism (see also reviews by Zucker and Regehr 2002; Fioravante and Regehr 2011; Hennig 2013). Notably, mechanisms 1 and 2 listed below do not require a specialized facilitation site or process, while mechanisms 3–5 rely on an extra Ca^{2+} -sensitive site which is either more remote from the Ca^{2+} channel, has a higher affinity for Ca^{2+} , or is slower than the fast low-affinity site responsible for baseline (initial) exocytosis rate and situated in close proximity to a Ca^{2+} channel. Detailed implementations of biophysical models 2–5 must include two ingredients: (1) model of Ca^{2+} dynamics (either a partial differential equation for Ca^{2+} concentration, a stochastic Monte Carlo simulation of Ca^{2+} ion movement, or a simplified ordinary differential equation description) and (2) a model of Ca^{2+} binding to Ca^{2+} sensors controlling exocytosis and its facilitation (usually described by mass-action Ca^{2+} -binding reactions).

Activity-Dependent Increase in Presynaptic Ca^{2+} Influx

The most direct facilitation mechanism is provided by the activity-dependent increase in the Ca^{2+} current through presynaptic voltage-dependent Ca^{2+} channels during the stimulus train, observed in some synapses. Such increase can be either caused by depolarization directly (Bertram et al. 2003; Brody and Yue 2000) or by

Ca^{2+} entering as a result of such depolarization and activating second messengers such as calmodulin or neuronal calcium sensor proteins, which interact with the channels and increasing their conductance (Mochida 2011). It is believed that this mechanism contributes to facilitation observed in certain conditions at the calyx of Held synaptic terminals (Catterall et al. 2013; Xu et al. 2007). However, in many synapses facilitation can be elicited without an increase in presynaptic Ca^{2+} current (Neher and Sakaba 2008).

Facilitation of Ca^{2+} Transients Through Buffer Saturation

The appealing property of the so-called buffer saturation mechanism is that it does not require any specialized facilitatory Ca^{2+} -binding site or process. Instead, facilitation in this case is explained by direct increase in local microdomain free Ca^{2+} achieved in the vicinity of a Ca^{2+} channel during each successive action potential, caused by the progressive reduction of free buffer capacity as it is gradually depleted by Ca^{2+} entering during the conditioning pulses. First proposed on the basis of computational modeling (Klingauf and Neher 1997), buffer saturation was later shown to contribute to facilitation at calbindin-positive neocortical and hippocampal synapses (Blatow et al. 2003; Burnashev and Rozov 2005) and other central synapses (Maeda et al. 1999; Felmy et al. 2003; Jackson and Redman 2003; Orduz and Llano 2007). This mechanism can also be described as a consequence of superlinear summation of small residual free Ca^{2+} accumulation, by itself too small to elicit facilitation, with the Ca^{2+} entering during an action potential; the nonlinearity of this summation is explained by the nonlinearity of the Ca^{2+} -buffer concentration relationship (Neher 1998a). Although the simplicity of this model is very appealing, its role is still under debate (Bornschein et al. 2013), and it imposes strict requirements on the properties of the Ca^{2+} buffer; in particular, simulations show that buffer saturation should be achieved in a large

portion of presynaptic terminal, which requires optimal concentrations of very fast and diffusible buffers (Matveev et al. 2004; Muller et al. 2005). Saturation of large concentration of immobile buffers would also lead to increase in Ca^{2+} transients but would produce much more pronounced elevation of free residual Ca^{2+} ; therefore immobile buffers are more likely to contribute to mechanism 4 below.

Bound Residual Ca^{2+} Accumulation

According to the bound residual Ca^{2+} model, facilitation results from the gradual increase in the Ca^{2+} -bound state of one or more Ca^{2+} sensors regulating exocytosis, rather than from an increase in free Ca^{2+} concentration, and therefore facilitation time course is entirely determined by the slow time scale of Ca^{2+} unbinding from these slow Ca^{2+} sensors that modulate exocytosis together with the fast Ca^{2+} -sensitive exocytosis trigger. This was historically the first conceptual model of facilitation first formulated by Katz and Miledi (1965) and Rahamimoff (1968), and realizations of this mechanism provided some of the first detailed models of facilitation (Yamada and Zucker 1992; Bertram et al. 1996; Delaney and Tank 1994; Dittman et al. 2000). To reconcile this mechanism with the observed sensitivity of facilitation to application of exogenous Ca^{2+} buffers, more up-to-date realistic implementation of this model involves simulations of free Ca^{2+} diffusion from the channel to the binding site, which confers to this model the required partial sensitivity to free Ca^{2+} (Yamada and Zucker 1992; Bennett et al. 2004; Matveev et al. 2006; Nadkarni et al. 2010).

Free Residual Ca^{2+} Accumulation at a Remote Site (Two-Site Model)

Although the growth of free residual Ca^{2+} is small compared to the high Ca^{2+} concentration achieved in the vicinity of a Ca^{2+} channel-vesicle complex,

it can still account for facilitation if exocytosis is assumed to be controlled by two independent Ca^{2+} -sensitive sites, one of which is located close to the channel and therefore controlled by fast microdomain Ca^{2+} transients coinciding with each action potential, and another lower-affinity Ca^{2+} -sensitive site located further away from the channel (perhaps shielded by the vesicle itself or other diffusion barrier), where the small accumulation of residual Ca^{2+} is comparable to the smaller peak Ca^{2+} reaching this more remote location. Thus, this model can be referred to as a *two-site model*. It should be noted that the presence of fixed buffers can aid in residual Ca^{2+} accumulation, since immobile Ca^{2+} buffers act as a Ca^{2+} trap, binding Ca^{2+} close to the vesicle-channel complex and slowly releasing it between action potentials (Neher 1998b). Biophysical implementations of the two-site model require simulations of Ca^{2+} diffusion and buffering (Matveev et al. 2002; Tang et al. 2000).

Calcium-Dependent Acceleration of Vesicle Mobilization

Vesicles undergo several biochemical steps such as docking and priming before becoming competent for exocytosis, and like exocytosis itself, these steps are Ca^{2+} dependent. Therefore, facilitation may arise from acceleration of such “vesicle pool mobilization” in response to Ca^{2+} elevation, increasing the number of vesicles available for release rather than increasing the probability of release of any individual vesicle (Sorensen 2004; Neher and Sakaba 2008). This mechanism would also explain acceleration of recovery from short-term synaptic depression observed in many synapses (Dittman and Regehr 1998; Stevens and Wesseling 1998; Wang and Kaczmarek 1998; Fuhrmann et al. 2004; Hosoi et al. 2007). It is possible that the last priming steps involve a geometric change in the active zone morphology, reducing the channel-vesicle distance (Gentile and Stanley 2005; Wadel et al. 2007), an effect termed “positional priming” (Neher and Sakaba 2008).

Although these effects are biologically very different from the mechanisms discussed earlier, corresponding facilitation models share formal similarities with both the two-site model and the bound- Ca^{2+} model discussed above. Namely, like in the two-site model, exocytosis is dependent on the combined action of two separate Ca^{2+} -sensitive processes, with the fast low-affinity exocytosis process sensing microdomain Ca^{2+} and ensuring phasic synaptic response, and the second high-affinity “priming” process responsible for facilitation controlled by smaller elevations of global Ca^{2+} outside of the microdomain. This mechanism also shares the characteristic property of the bound- Ca^{2+} model in that exocytosis is not in instantaneous equilibrium with local Ca^{2+} concentration, since the priming reactions are at best only slowly reversible. Earlier models of Ca^{2+} -dependent mobilization are based on ordinary differential equations (Dittman et al. 2000; Worden et al. 1997), with more recent models incorporating Ca^{2+} diffusion and buffering to account for the pronounced effects of Ca^{2+} buffering on synaptic facilitation (Millar et al. 2005; Pan and Zucker 2009).

Hybrid Mechanisms

We note that the above mechanisms are not mutually exclusive, and several of them may contribute to facilitation at a particular synaptic terminal. For example, in one of the most detailed recent studies of exocytosis and its short-term plasticity involving stochastic Monte Carlo simulations of Ca^{2+} ion dynamics, both free and bound residual Ca^{2+} accumulation contributes to facilitation (Nadkarni et al. 2010, 2012).

Other Models

A more controversial possibility is that exocytosis depends on voltage explicitly, apart from its Ca^{2+} dependence (see review by Debanne et al. 2013). In this case the fast and brief time course of exocytosis is primarily determined by the fast dynamics of membrane potential and can be achieved even if

the primary exocytosis sensor is shielded from the high Ca^{2+} microdomain or located further from the Ca^{2+} channel. In this case the exocytosis sensor’s affinity for Ca^{2+} would be sufficiently high to be sensitive to even small accumulations of residual global free Ca^{2+} , which would be comparable to peak Ca^{2+} achieved during the action potential at this remote or shielded location (Parnas et al. 1986). It is clear that this mechanism can be viewed as a modification of the free residual Ca^{2+} accumulation model (mechanism 4).

Failure of Averaging

Mark S. Goldman

Center for Neuroscience, Department of Neurobiology, Physiology, and Behavior, Department of Ophthalmology and Vision Science, University of California, Davis, CA, USA

Definition

Failure of averaging refers to the situation in which the behavior generated using the average of a set of measurements is not representative of the behavior of the measured population. Averaging fails when the set of parameters describing a system occupies a strongly concave-shaped region in the parameter space, so that the centroid of the distribution of measured parameters does not lie within the distribution itself. Failures of averaging may result either when individual parameters have multimodal distributions or when multiple parameters are correlated in such a manner that their joint distribution is concave. In the latter case, failure of averaging may be difficult to detect experimentally if the set of parameters whose correlations lead to failure of averaging cannot be measured simultaneously.

Detailed Description

Background and Overview

A common technique throughout the sciences is to pool data over many trials or samples and compute the average. This is commonly done to reduce variability due to measurement noise or intrinsic variability irrelevant to the signal of interest. However, this procedure can fail when the response of a system can be produced through multiple different sets of underlying parameters whose average is not typical of any individual measurement.

In the case of a system parameterized by a single variable, failure of averaging can occur if the set of stimuli that trigger a particular response

occupies a bimodal distribution. For example, if a hypothetical motion-sensitive neuron is responsive to horizontal motion with speeds around 5 m/s but is insensitive to the direction of movement, then the set of stimuli leading to an action potential may be described by a bimodal distribution similar to that shown in Fig. 1a. In this case, the strongly concave distribution is such that the mean stimulus leading to an action potential, corresponding to a stationary stimulus, never itself causes neuronal firing.

In higher dimensions, failure of averaging correspondingly can occur if the set of stimuli leading to a given response forms a concave region of parameter space so that the mean is not representative of the distribution from which it was generated (Fig. 1b, left). Furthermore, when the parameter space has a concave shape, the covariance ellipse representing one standard deviation about the mean may only minimally overlap the data from which it was constructed (red ellipse). In this case, not only does averaging together the data fail but even the second-order statistics (means and covariances) fail to characterize the data well.

More generally, the examples above show that failure of averaging occurs in situations where higher-order correlations are critical to describing the structure of a data set. In many settings, such parameter covariations may not be directly measurable, either because the measurement technique requires averaging of many samples to obtain sufficiently high signal to noise or because only a small number of system parameters can be measured at any one time. An illustration of this is provided in Fig. 1c, which shows the marginal distributions (distributions over one parameter, after summing over all samples of the other parameter) for the two-dimensional data set of Fig. 1b. Each of the parameters x_1 and x_2 individually has relatively unstructured distributions (Fig. 1c), so that it is not evident from these marginal distributions that averaging would fail so catastrophically. Indeed, taking random combinations of x_1 and x_2 leads to a relatively unstructured distribution (Fig. 1b, right), illustrating that it is the structure of the correlations in the data set that leads to a failure of averaging.

F

Failure of Averaging, Fig. 1 Geometry of failure of averaging. (a), Failure of averaging when the observed response is controlled by a single parameter, such as for the hypothetical horizontal-motion-tuned neuron discussed in the text. The parameter values leading to the response occupy a strongly bimodal distribution, so that the average is not a member of the parameter set itself. (b, c), Failure of averaging in higher dimensions. (right) The data points

(blue) occupy a concave region of parameter space that does not contain its mean (red point) or most of the region enclosed by the covariance ellipse (red ellipse). This failure of averaging is caused largely by the correlations between x_1 and x_2 because the marginal distributions of these parameters (c) and the distribution generated by randomly pairing x_1 and x_2 values (b, right) are relatively uniform

Examples of Failures of Averaging

Conductance-Based Modeling of Neurons

The electrical properties of single neurons arise from the coordinated interplay of many different types of ion channels. The maximal conductances of each of these ion channels can vary widely from cell to cell, even in identified neurons of the same cell class that exhibit similar firing properties. Traditionally, cell-to-cell variability in ionic conductance measurements was attributed to noise or independent parameter variations and was averaged away to give a single, canonical value of the maximal conductance of a given channel in a particular neuronal subtype. These canonical values were then used as the starting point for constructing conductance-based neuron models. However, a series of studies (reviewed by Marder 2011) has shown how nearly identical

behavior of single neurons or small networks can emerge from widely varying sets of underlying conductance parameters. If these conductance parameters sit in a concave region of parameter space, then a model constructed from the average of the measured conductances will not be representative of the cell's experimentally measured response.

An example of such failure of averaging, taken from a computational model of an identified neuron in the crustacean stomatogastric system (Goldman et al. 2001; Golowasch et al. 2002), is shown in Fig. 2. A brute-force search over thousands of models generated by random combinations of five different maximal conductance parameters was used to identify combinations of conductances that lead to "single-spike burster" firing patterns with a single fast Na^+ action potential riding on top of a slower Ca^{++} action potential

Failure of Averaging, Fig. 2 Failure of averaging in a conductance-based neuron model. (a, b), Voltage waveforms (a) of three examples from the L-shaped distribution of models producing one-spike bursting behavior (b). Each example has a highly similar voltage waveform even though the different examples have maximal conductance values $g_{\max} \text{Na}$ and $g_{\max} \text{Kd}$ that are high for Na and low for

Kd (point 1), low for both channels (point 2), or high for Kd and low for Na (point 3). Other data points in b correspond to non-bursting models or models with different numbers of spikes per burst. (c), A model constructed from the mean of all one-spike bursters is not itself a one-spike burster (Adapted with permission from Golowasch et al. (2002))

(Fig. 2a, three examples). When the maximal conductance values of the sodium (Na) and delayed rectifier potassium (Kd) conductances of all single-spike bursters were analyzed, they were found to individually vary over orders of magnitude and to covary such that they formed an L-shaped region in parameter space (Fig. 2b, blue points). As a result, a model constructed from the average of these single-spike bursters did not correspond to a single-spike burster but instead gave rise to a far different pattern of firing, with three spikes per burst. Mechanistically, the L-shaped region reflected that single-spike bursting activity could occur when there was insufficient Na^+ conductance to produce a second spike during the burst (Fig. 2b, low $g_{\max} \text{Na}$ values) or insufficient K^+ conductance to repolarize the action potential sufficiently to enable a second

spike during the burst (Fig. 2b, low $g_{\max} \text{Kd}$ values). More generally, this example reflects how a relatively precise behavioral output (single-spike bursting) can be produced from a broad range of underlying parameters whose strongly nonlinear correlations confound attempts to associate the behavior with a single “canonical” set of parameters such as the means of the measured population.

Failure of Averaging in Neural Coding

Another common setting in which failures of averaging are common is in neural coding studies. A hallmark of neurons in later stages of sensory processing is the simultaneous invariance of their responses to certain features of sensory stimuli and strong selectivity to other features. This creates problems for classic correlation-based

methods for characterizing sensory neuron responses, such as the spike-triggered average, that attempt to determine a neuron's selectivity by calculating the average stimulus that precedes a set of neuronal spikes. For example, in the case of the hypothetical speed-tuned neuron of Fig. 1a, the average stimulus preceding a spike has zero velocity and does not itself trigger spiking in this neuron. A similar failure of spike-triggered averaging occurs in the characterization of complex cells of the primary visual cortex that respond to oriented gratings of light and dark bars in a manner that is largely invariant to the phase of the alternating light and dark stripes (Touryan et al. 2002; Schwartz et al. 2006). In the case of complex cells, the use of higher-order statistics such as the spike-triggered covariance of the stimulus set can reveal the underlying selectivity. However, in higher areas of the visual system, even spike-triggered covariance analysis may fail, because cells exhibit more strongly nonlinear feature selectivity while remaining highly invariant to the pairwise correlations among stimulus elements probed by spike-triggered covariances (DiCarlo et al. 2012).

Failure of Averaging in Detecting Discrete State Transitions

A common feature in many biological systems is the presence of discrete states of activity between which a system may stochastically switch. However, differentiating between systems that encode information through continuous variations in activity versus those that utilize discrete activity states can be challenging. The problem in distinguishing such transitions is that neural spike trains are noisy, so that detecting jumps in activity typically requires averaging across many trials. This presents a problem when the time of the jump in activity varies from trial to trial, because the average of many trials can lead to the impression of a graded change in firing rate (Fig. 3a, red) even if each individual trial contains a discrete jump (Fig. 3a, black). An example of such a failure of averaging was suggested by a study of neurons in the gustatory cortex during taste processing. Recording the activity of a large ensemble of neurons revealed, on each trial, discrete transitions between a finite set of stereotyped states defined by the relative firing patterns of neurons across the electrode array (Jones et al.

Failure of Averaging, Fig. 3 Failure of trial-averaging in detecting discrete jumps in activity. (a), Cartoon example illustrating failure of trial-averaging. On each individual trial (black), activity discretely jumps to a non-zero level, but the jumps occur at different times on each trial. Averaging across trials leads to the appearance of a smooth increase in activity (red). (b), Example of failure of trial-averaging in taste processing. Averaging a single

recorded neuron's action potential discharge across trials led to an apparently graded increase in firing rate (green). Aligning instead on the multi-neuron population transition revealed a consistent, discrete jump in firing rate of this neuron at the population transition (blue). The presence and timing of the multi-neuron state transition was determined with a hidden Markov model (Adapted with permission from Miller and Katz (2010))

2007; Miller and Katz 2010). However, the times of these transitions differed markedly from trial to trial so that averaging across trials, with time aligned on the trial start, led to the appearance of graded changes in firing rate (Fig. 3b, green). Aligning instead on the state transitions identified by a multi-neuron pattern analysis revealed sharp transitions between states on a much faster time scale (Fig. 3b, blue).

Implications for Experiments

The failure of averaging demonstrated in the above examples is inconvenient for simple characterizations of data by means and variances but may not be problematic if all of the parameters of a system can be measured simultaneously and fit by a model that includes nonlinearities or higher-order statistics. However, in many biological situations, population data are either implicitly averaged by the measurement technique, such as when large numbers of cells are homogenized together to increase the signal-to-noise ratio in gene expression studies, or only a small number of system parameters can be measured simultaneously.

In the absence of simultaneous measurements of all relevant system parameters, it is important to ask whether the population means of the measured samples are likely to be representative. In the cases illustrated above, the unmeasured correlations between the parameters were highly nonlinear and caused the population mean to differ entirely from the individual samples from which it was generated. In the less extreme case, the mean parameter set might lead to an output consistent with the data from which it was determined. However, the variability around this mean would not necessarily represent noise but instead could represent the multiplicity of ways in which biological systems can produce a given output (Foster et al. 1993; Bhalla and Bower 1993; Goldman et al. 2001; Prinz et al. 2004). Given the ability of biological systems to produce desired outputs through multiple underlying mechanisms, “failure of averaging” in this broader sense may be a common occurrence.

Definition

FieldML (Christie et al. 2009; Britten et al. 2013) is a proposed open standard data format for representing mathematical models, developed at the Auckland Bioengineering Institute (ABI) at the University of Auckland, New Zealand. It is specifically focused on multivariate spatiotemporal models and finite element method (FEM) models for biological modeling, but can be used more generally. FieldML version 0.5 is the most recent release (2012) at the time of writing, and although it already comprehensively supports the representation of a wide range of relevant models, the format is still considered under development.

Detailed Description

Introduction

Mathematical models form a core part of computational bioscience. Often these models are either represented using mathematical symbols intended to be read by humans (such as in books or research papers) or in computer programs using the

mathematical operators and syntax of a particular programming language. These approaches limit the usefulness of the model, requiring manual coding to reimplement the models in new modeling contexts and often not cleanly separating the mathematical model from the numerical methods used to compute the model.

A number of modeling formats have been created to address this problem, for example, NeuroML, CellML, and SBML. FieldML (www.fieldml.org) follows a similar approach, but with a focus on the representation of the following:

- Anatomical shape (or geometry)
- Spatially varying quantities
- Time-varying quantities
- Generalized multivariate mathematical fields

Although these biomedical focus areas have played a key role in guiding the design, FieldML is not restricted to biomedical modeling and is potentially useful in more general mathematical modeling contexts.

Overview of Data Model

FieldML top-level models are serialized to the FieldML XML format, and other data formats can be referred to from the XML for the purpose of separating bulk data from the higher-level model description. Bulk data usually consists of large numerical arrays. Underlying the XML format is the abstract FieldML data model that is independent of XML and indeed could be serialized using a different technology. The FieldML data model can also be used directly as the in-memory representation by software that processes mathematical models. This subsection gives an overview of the FieldML data model. A more detailed description of both the FieldML version 0.5 data model and the corresponding XML format is available in Britten et al. (2013).

The two main objects of interest in the FieldML data model are fields and domains. Domains are mathematical sets, possibly with additional information about their topology. An example of a domain is the set of real numbers.

Fields are mathematical functions that map values from one FieldML domain to another FieldML domain. An example of a mathematical function that could be modeled as a field would be the cosine function. Note that the term “domain of a function” is used in mathematical terminology to mean the set from which a function maps values, and similarly, the “codomain of a function” is the set into which a function maps values. The domain of the cosine function is the set of real numbers. The codomain is also the set of real numbers. Since the term domain is used for two different meanings, clarification is achieved by using the terms “FieldML domain” and “function domain” whenever confusion is possible.

The standard mathematical notation for stating that a function f has the set A as its domain and the set B as its codomain is as follows:

$$f : A \rightarrow B$$

In FieldML, fields are constructed by chaining together *evaluators*. A FieldML evaluator represents a function, and the “chaining” is essentially function composition. This will be elaborated upon later on in this section.

Evaluators

In FieldML 0.5, there are seven kinds of evaluators: argument, parameter, piecewise, aggregate, reference, external, and constant.

An *argument evaluator* essentially performs the role that a variable performs in algebraic mathematical expressions.

A *parameter evaluator* defines a function that essentially represents a numerical array by means of the array indexes being treated as the function’s parameters. The actual values of the array elements are retrieved from data sources, which are described later in detail, but essentially are bulk data, usually for numerical arrays.

A *piecewise evaluator* defines a piecewise function, where the function domain is a discrete set.

An *aggregate evaluator* defines a vector-valued function, for example, a function that takes values in three-dimensional Cartesian space.

A *reference evaluator* can be either just an alias for another evaluator or, if used in conjunction with binding (described below), represent the substitution of values into the expressions represented by a pipeline of evaluators.

An *external evaluator* declares the existence of an evaluator whose behavior is defined outside of any FieldML file. This is essentially a work-around for a current limitation of FieldML version 0.5 where common algebraic operators such as addition and multiplication are not yet supported. The work-around allows FieldML models to refer to functions that are required for the target usage, and relies on external documentation of the intended behavior and consistent implementation in all software that processes FieldML version 0.5. Although this also allows arbitrary nonstandard extension, it is discouraged. This is seen as an interim measure until the next version of FieldML is released with features that allow these functions to be defined directly in FieldML itself. The intention is that the use of external evaluators should be limited to using only those already provided in the standard library (described below) that is included as part of FieldML version 0.5.

A *constant evaluator* represents a constant value, with the restriction that it must be possible to represent the value type using standard XML string representations, which means that only text, integer, and floating point values can be represented. In combination with other evaluators, more complex constants, such as a constant vector value, can be represented.

As mentioned earlier, *binding* essentially represents the process of variable substitution in mathematical expressions. Binding can be specified as part of the specification information for reference, piecewise, and aggregate evaluators. The information provided as part of the binding syntax specifies the name of an argument evaluator and the name of any other evaluator type which will be the substitute evaluator. It represents the action of substituting every occurrence of the specified argument evaluator in the pipeline “upstream” of the host evaluator.

Domains

In FieldML version 0.5, the following constructions can be used to define domains: ensemble, Boolean, continuous, or mesh.

Note that two different domains are treated as distinct sets, even if their definitions are identical.

Ensemble is used to define finite discrete sets where the labels used for a given ensemble are either all integer labels or all string labels.

Boolean declares that a given set has exactly two members, labeled *true* and *false*. Predicate functions are used as part of the definition syntax for mesh domains (described below), and their codomain must be any domain that has been declared to be Boolean. A Boolean domain is defined in the FieldML version 0.5 standard library, and it is recommended that this be used whenever a Boolean domain is required, rather than defining additional Boolean domains.

Continuous is used to declare n -dimensional Cartesian space (however, this excludes any additional algebraic structure, such as vector addition, a distance metric, or a Riemannian metric). For dimensions higher than 1, the definition allows for an ensemble to be designated as the labels for each dimension, for example, “u, v” or “x, y, z.”

Mesh is used essentially to define a FEM mesh where all elements are the same dimension; however, the element shape may vary. Element shape is defined by reference to a predicate, which is any evaluator with a Boolean codomain. A collection of such predicates are provided in the FieldML version 0.5 standard library, and all of these are defined as external evaluators. The mesh declaration includes the definition of an ensemble that indexes the elements of the mesh and a continuous type that is used for the coordinates within each element. FieldML version 0.5 does not have a way of specifying the connectivity of the mesh. The fields over the mesh, such as the geometry field or any other fields, are defined by means of creating an evaluator pipeline. This will usually require a piecewise evaluator which depends on parameter evaluators for the degrees of freedom (DOFs) and the local to global node mapping. Hence, the connectivity information is usually present in an indirect manner.

Data Sources

Data sources allow the FieldML file to refer to bulk numerical data that is either stored in the same FieldML XML file, an imported FieldML XML file, or an external file. Data stored in external files can be stored as decimal strings in text files, or using HDF5. Parameter evaluators make reference to data sources for their data. The location of external data files is specified by URL.

Imports

Imports allow a FieldML XML file to make reference to evaluator declarations or domain declarations from external FieldML XML files. Imports require that an alias be assigned by which the imported entities are referenced. These are then treated as if they had been defined locally. Entities on which they depend are not available locally, but are nevertheless still part of the definition of the imported entities. The location of the imported XML files is specified by URL.

Imports allow FieldML models to be composed in a modular fashion, which encourages reuse and allows for duplication to be kept to a minimum.

FieldML Standard Library

The FieldML standard library serves two main purposes for version 0.5. Firstly, it provides reusable centralized definitions of evaluators and domains that are commonly required in the target application areas of computational physiology and bioengineering modeling. Secondly, in conjunction with the FieldML specification, it documents the external evaluators so that the required convention is established.

The FieldML standard library is available from http://www.fieldml.org/resources/xml/0.5/FieldML_Library_0.5.xml.

The FieldML Version 0.5 API

The FieldML version 0.5 application programming interface (API) and API implementation

were released in conjunction with the FieldML version 0.5 format. The API consists of functions for both serialization to XML and deserialization from XML. The implementation is written in C++, and bindings are provided for C++, C, Java, and Fortran 90.

Adoption

At the time of writing, known adoption of FieldML is still relatively low. The ABI hosts three software projects which have limited FieldML support. Firstly, the OpenCMISS-Zinc software library uses the FieldML API to allow for 3D interactive model visualization for a limited range of models. Secondly, the Physiome Model Repository (PMR) software allows for FieldML models stored in the model repository to be visualized using the Zinc plug-in, which is a browser plug-in based on the OpenCMISS-Zinc library. Thirdly, the OpenCMISS-Iron computational system can use the FieldML API to read in a limited range of mesh and field definitions from FieldML and can output some types of simulation results in the FieldML format also by using the FieldML API.

Definition

Figure-ground segregation refers to the capacity of a visual system to rapidly and reliably pick out for greater visual analysis, attention, or awareness, or preparation for motor action, a region of the visual field (figure) that is distinct from the combined areas of all the rest of the visual field (ground). The “figure” region is often, but not necessarily, bounded by a single closed visual contour, and the figure region is often said to “own” the boundary between it and any adjacent regions. The figure region is generally experienced as “in front of” (along lines of sight) surfaces of objects that are in the ground region. Once figure-ground segmentation is achieved, the figure region often delineates a zone of additional attentive visual processing.

Detailed Description

The Importance of Figure-Ground Segregation

Visual function in animals has broadly increased in complexity and competence across eons of evolution, with figure-ground perception being among the later and more intriguing achievements of relatively sophisticated visual species.

The importance of figure-ground perception can be seen by considering its advantages to animals that have the capability, as compared to the visual limitations of animals whose visual systems do not support figure-ground perception (Land and Nilsson 2002). For example, the single-celled euglena can use its eyespot and flagellum to orient its locomotion in a light field, but it cannot take account of the edges of individual objects in the sense of figure-ground for purposes of steering. Arrays of visual receptors that sample different directions of the visual field, such as the compound eyes of insects or mammalian retinas, are needed for computing figure-ground relations. Successful figure-ground segregation can facilitate several subsequent visual tasks, such as object recognition or guidance of locomotion toward a goal or around an obstacle.

Some species of animals can perform figure-ground perception only in the presence of visual motion, while others can also do so in static environments. It must be noted that even when the environment outside an animal is perfectly still, the animal itself may be making voluntary movements at a macroscale or involuntary movements (eye tremor or microsaccades) that can help to support figure-ground segregation.

Finally, as we will see in the case of human (or, more generally, primate) figure-ground perception, the space-variant arrangement of receptors on the retina and the associated “cortical magnification” that concentrates the brain’s processing resource to the central region of the visual field are major factors both in achieving and in exploiting figure-ground perception. Voluntary eye movements to an approximate centroid of a relatively homogenous visual region can enhance the visual system’s capacity to delineate an associated figure-ground boundary and thus to perform figure-ground segregation at all. Conversely, as long as the eyes are foveating a “figure” region, a high proportion of cortical tissues is devoted to analysis of that region, courtesy of cortical magnification, thus facilitating object recognition or discrimination between two similar object categories. The ability to deploy foveal vision while performing figure-ground segregation can thus be viewed as

a “force multiplier” that enables detailed scrutiny at relatively low metabolic cost (eye movements), rather than requiring a reorientation of an entire head or actual approach of the entire body toward an environmental region.

Elementary Cues for Figure-Ground Segregation

In visual scenes with little structure, separation of figure from ground may appear as an easy or even trivial task. For example, a small dark spot on an otherwise homogenous light background is often said to “pop out” from its background in the context of a visual search task (e.g., “Find the dark spot,” Treisman and Gelade 1980). Such isolated, salient figural properties “call attention to themselves” and are effective as lures that attract saccades. A consensus of recent decades holds that regions of higher-than-average (relative to the rest of the scene) activation of certain featural qualities (e.g., of color, contrast, motion, or orientation) in visually topographic “feature maps” make such regions likely targets for attention or of overt eye movements (Wolfe and Horowitz 2017).

An important class of figure-ground phenomena occurs in cluttered visual scenes, where the achievement of figure-ground segregation can amount to the breaking of camouflage. Gibson et al. (1969) demonstrated vivid figure-ground segregation in random dot kinematograms – displays involving some combination of static and moving randomly distributed dots that are analogous in the time/motion domain to random dot stereograms. In random dot stereograms, two eyes receive related, but different, images, typically where a region of dots (the figure) is displaced in one eye’s view relative to the other eye’s view, causing a relative disparity of stimulated retinal locations that is different from the disparities of other corresponding dots in the two eyes (which form the ground).

The importance of motion to figure-ground perception of ecological scenes has been evident since, at least, the seminal paper by Lettvin et al. (1959) “What the frog’s eye tells the frog’s brain,” whose authors noted that frogs of the studied species would starve in the presence of freshly

killed flies spread on the ground before them. Nonetheless, humans and certain other species have the capacity to perform figure-ground segregation for many complex static scenes, including pictures – for which endogenous eye movements convey no additional information, as would be the case for views of actual three-dimensional environments.

The Scope of the Present Article

This article focuses on computational models of human or primate figure-ground segregation. We indicate whether models are intended to address moving or static scenes, or both, and whether they rely on binocular vision. Reasons for this focus include (1) that primate visual systems have the greatest complexity and competency among known biological systems and (2) that many machine vision systems are designed with the intent of matching if not exceeding human performance in important visual tasks. While many computer vision algorithms are designed without reference to animal examples, it makes sense to study natural visual systems for inspiration in those domains for which machine performance continues to lag, as is the case with figure-ground segregation in cluttered scenes.

What Is Border-Ownership and How Is It Related to Figure-Ground Perception?

A “figure” object and its borders occlude the objects and their borders of the background. Figure 1a shows the famous painting by Leonardo da Vinci: Mona Lisa occludes the trees, river, bushes, and other objects in the background.

The foreground borders in (Fig. 1a) obviously “belong” to the object (i.e., Mona Lisa) in front, which is the figure. The shape of the borders is often informative about the identity of the object (a human) that is depicted, which is said to “own” the border – thus figure-ground perception can be an important step on the way to object recognition. Note however that Evans and Treisman (2005) have shown that people can perform animal detection in natural scenes with great success even though they are unable to localize the animal, so figure-ground perception cannot be said to be a required step in object recognition. Rather, the *localization* of a figure’s borders and proper assignment of the ownership of associated borders are logical requirements of figure-ground segregation.

Border-Ownership Is Independent from the Polarity of Contrast Across Borders

A clever artist can devise displays in which the ownership of a border is ambiguous, leading to

Figure-Ground Segregation, Computational Neural Models of, Fig. 1 Examples of 2D images helping formulate the concept of figure-ground segregation and border ownership, irrespective of some visual attributes such as edge contrast. (a) Mona Lisa by Leonardo da Vinci.

F

Figure-Ground Segregation, Computational Neural Models of, Fig. 2 Figure-ground segregation during camouflage, when the figure and background have similar textures and their average luminance are close to each other. Such scenes can pose another level of challenge to computational models of figure-ground segregation, as the

figure borders cannot be readily detected by the lining up of the units detecting edge contrast, as tiny edge contrasts with different orientations are almost uniformly distributed. (Adapted from pixabay.com; photo is released under CC0 Creative Commons)

bistable percepts. See Fig. 1b, the Rubin (doctoral dissertation 1915) faces/vase. While consciously experiencing the faces against a black background, the borders separating the white and black areas are the face borders. Note that flipping the contrast of Fig. 1b and making the faces black and the vase white (Fig. 1c) do not change the relationship between the figure-ground separation and border-ownership, i.e., when the faces are seen against the uniform background, the borders between the black and white areas belong to the faces and the same for the vase.

A good deal of attention in introductory textbooks is devoted to bistable displays (Fig. 1b–c) when discussing figure-ground perception. Although such displays help to make an important point about the relationship between figure-ground relations and border-ownership, they are a potentially misleading starting point relative to figure-ground perception in natural scenes. In bistable displays, volitional manipulation by the viewer of semantic categories such as face or vase can “drive” a resulting percept. The bistability of labeling border-ownership is not typical of most normal perceptual settings, which are closer to the depiction of Fig. 1a. Note

also that finding boundaries is trivial in binary-valued displays with solid, connected regions, such as Fig. 1b and c, as opposed to conditions of, for example, animal camouflage (Fig. 2).

Psychophysical Antecedents of Recent Computational Neuroscience of Figure-Ground Perception

The second half of the twentieth century saw a great deal of human psychophysics devoted to the study of texture segregation, visual segmentation and grouping, and visual search.

Linking these studies – many of which sought to find fundamental visual “elements” of perception – was the goal of characterizing how, out of the “blooming, buzzing, confusion” of time-varying visual scenes, our visual systems are able to focus on relatively coherent objects of interest (figures). The texture segmentation and grouping studies characterized conditions under which perceptually continuously connected boundaries between regions could form, even in the absence of continuous differences in luminance or contrast along those boundaries (such as is evident in Fig. 2). Thus, the question of “ownership” of boundaries was often not raised.

Visual search studies, pioneered by Anne Treisman in the 1980s (Treisman and Gelade 1980) and developed since by many, most notably Jeremy Wolfe (Wolfe and Horowitz 2017), focused on describing conditions under which a region of a scene would “pop out” and thus be treated as a “figure” for subsequent processing, with the rest of the display acting as “ground.” When conditions for pop-out were not in play in a given display, search could be “guided” by top-down expectations (Wolfe and Horowitz 2017), or a number of candidate regions (Grossberg et al. 1994) might be evaluated in order of likelihood of containing the object being searched for. In scenes containing an object of search, the finding of that object, whether quickly or slowly, inevitably is accompanied by the phenomenal experience of the visible regions of that object as “figure.” A series of psychophysical studies led in turn to related paradigms involving brain imaging or electrophysiological recordings in primates, which have advanced our understanding of figure-ground perception tremendously.

Finally, an important thing to note about figure-ground perception is that, unlike the examples discussed to this point, in daily life it does not generally occur in a flat plane, such as in a picture. When we look at a spoon or cup that we are about to reach for, the surface of the object is extended and often curved in three dimensions. Tyler and Kontsevich (1995) introduced the important concept of an “attentional shroud” – a fuzzy manifold in perceptual space that envelopes the surfaces of attended objects. The shroud delineates both the limits of focal attention and also the tendency of attention to involuntarily “spread” along the visible surfaces of an attended figure, rather than into the rest of the scene (the ground). Indeed, the delineation of attentional resources for visual processing after the determination of figure-ground segregation can be viewed as an important functional reason for engaging in figure-ground segregation in the first place.

Brain Areas Involved in Figure-Ground Perception

Although figure-ground segregation is fundamental to visual perception, how the visual system

performs it is not well understood. Coding of border-ownership starts early in primate brain visual stream. A direct link between visual figure-ground perception and the responses of certain single neurons has, however, been established in the early visual system.

These cell responses may require the simultaneous activation of parts of visual areas V1, V2, and V4 (Fig. 3) acting as a functional network (Layton et al. 2012), whose neurons are monosynaptically connected to each other across visual areas (Fig. 3b). Such connections are termed *inter-areal*. On the other hand, neural connections within each area (i.e., V1, V2, etc.) are called *intra-areal*. Zhou et al. (2000) and Ko and von der Heydt (2018) have found that about half of sampled cells from primate visual areas V2 and V4 preferentially respond to borders whose ownership is related to figure-ground relations (Fig. 4). These cells are referred to as border or B-cells and have “side-of-figure” selectivity that indicates a neurophysiological correlate of percepts observed in Fig. 1b–c, namely, that a border is owned by either the region to one side (for example vase) or another of that border (face), but not both.

Temporal Dynamics of Border-Ownership Neural Response

The border-ownership-related neural response can emerge within 25 msec after the B-neuron’s response onset. In V2 and V4, the differences were found to be nearly independent of figure size up to the limit set by the size of the display (21°) that Zhou et al. (2000) used (Fig. 4). Because such a response depends on the processing of an image region that is at least as large as the figure and thus requires the transmission of information over some distance in the cortex, *these short delays constrain the functional network underlying the B-cell response and the biological plausibility of neural models.*

The short delay of the emergence of border-ownership signals constrains the contribution of inter-areal and intra-areal connections in a biologically plausible neural model that can perform figure-ground segregation (Layton et al. 2012). This is because inter-areal connections are

Figure-Ground Segregation, Computational Neural Models of, Fig. 3 Brain areas at some distance can be axonally connected, such as inter-areal connections between visual areas V1, V2, and V4. Inter-areal connections via myelinated axons are much faster than within area (intra-areal, unmyelinated) connections. As a result, during a stream of visual inputs, multiple brain areas can be activated within a short period of time, forming

a multiple-area network for processing the input. (a) Lateral view of the left hemisphere of a monkey brain, roughly showing the locations of V1, V2, and V4. (Adapted from Wurtz (2015) under the Creative Commons Attribution 4.0 International license). (b) A simple schema showing inter-areal and mutual connections between areas V1, V2, and V4, highlighting the fast inter-areal connections that can generate a functional multiple-area visual network

Figure-Ground Segregation, Computational Neural Models of, Fig. 4 The von der Heydt group discovered the presence of border-ownership neurons. The neuron receptive field is shown by small circle/ellipse which is over the figure edge. Local contrast (light/dark) is the same across each column and over the classic receptive field of

the neuron, yet, the neuron shows preference for figure to the left (1st row in a and b) than to the right (2nd row in a and b). Such cells, therefore, encode border-ownership, and in this particular case, left-side ownership. (Adapted from von der Heydt (2015) under CC BY License)

myelinated and transfer neural signals much faster than the intra-areal ones, and therefore, the small delays observed in border-ownership signals demand fast inter-areal connections. Researchers have proposed that B cells access global information either intra-areally, i.e., by lateral connections within a single visual cortical area, such as V2 (Zhaoping 2005), or inter-areally, i.e., where cells with larger receptive fields (e.g., V2) communicate contextual information about the scene via feedback projections to visual areas whose cells

have smaller receptive fields (e.g., V1; see the diagram in Fig. 3b). Intra-areal and inter-areal axonal conduction velocities have been estimated to be 0.3 and 3.5 m/s in early visual areas, respectively (Bullier 2001). Hence, inter-areal connections can be an order of magnitude faster than intra-areal connections for propagating information across the visual field. B-cell responses to 3° squares did not differ in latency compared to those to an 8° square, which is consistent with the use of inter-areal connections, but not intra-areal

connections, to propagate contextual figure-ground information. Although a variable amount of time is required to propagate information about a figure within a single cortical area, transmitting the information to another area with large receptive field cells could afford a roughly fixed delay irrespective of the figure size in the visual field (Layton et al. 2012). Hence, *it appears that connections within a single cortical area alone could not plausibly account for the fast global scene integration that is observed in B-cell border-ownership responses* (Layton et al. 2012), but see Zhaoping (2005), who argues otherwise.

The immediately preceding discussion is an example of an emerging paradigm shift in understanding of cortical visual processes. Most physiological studies related to cell response to luminance-based and hue-based edges of the primate visual system in the past half-century have followed the path established by Hubel and Wiesel (1962) and largely focused on the function of individual areas or subpopulations of cells *within a visual area*. Topics of such studies include how different cells in the primary visual cortex respond to luminance base edges, to the light-dark polarity of contrast, and to variations of edge orientation. It instead appears that the cortex can solve complex problems *with networks that span multiple areas*. The visual system may thus rapidly recruit an assembly of cortical areas to determine border-ownership in figure-ground segregation, a single emergent function. Neuroanatomical evidence indicates that early visual areas such as LGN, V1, V2, and V4 are massively interconnected with numerous feedforward and feedback connections (Sincich and Horton 2005, see Fig. 3b). Feedforward connections are believed to quickly propagate sensory visual information to cortical areas further up the visual hierarchy to serve a rich perception of the visual scene. Feedback projections are often said to play a modulatory role with respect to bottom-up sensory visual signals by increasing the gain of neuronal responses in attended regions and performing contextual integration. To date, few studies have hypothesized that feedback projections play a crucial as opposed to supplementary roles for the functions of early visual

cortices. It appears that the simultaneous activation of multiple areas early in the visual system not only performs modular functions that are later combined but also that such activation can collectively solve problems that individual cortical areas cannot solve alone (Layton et al. 2012).

A Teardrop Model of Figure-Ground Segregation and an Edge-Integration Model

Layton et al. (2014) presented a model of figure-ground segregation in which inter-areal feedback plays a crucial role in disambiguating a figure's interior and exterior. The model processes are based on primate receptive field scatter (jitter in receptive field center locations) and variation in receptive field sizes to generate a code for inside versus outside of a visible figure. Feedforward projections from V4 signal the curvature of object boundaries (curved contour cells), and feedback projections from visual temporal areas group neurons with different receptive field sizes and receptive field center locations in a teardrop geometry. Neurons sensitive to convex contours, which respond more when centered on a figure, balance feedforward information and feedback from higher visual areas. The model produces maximum activity along the medial axis of figures irrespective of the concavities and convexities of figure contour. The model feedback mechanism balanced with feedforward signals is crucial for figure-ground segregation and localization (Fig. 5).

Another computational approach in solving the figure-ground problem for static scenes is given by Grossberg (1993, 1994). This neural model involves feedforward and feedback interactions between cortical units that represent boundaries and surfaces at multiple spatial scales. The assignment of border-ownership drives interactions where signals for boundaries that are nearer to the viewer suppress signals for further-away boundaries in a way that supports featural visibility (lightness) of the figure region while allowing aligned segments of far boundaries to complete and support amodal completion of partially occluded surfaces. Note that, while differing in important ways from the Layton et al. (2012, 2014) models, the Grossberg (1993, 1994)

Figure-Ground Segregation, Computational Neural Models of, Fig. 5 Localizing a C-shaped (crescent moon shaped) figure is difficult from the perspective of a single neuron’s convex receptive field (shown as dotted black outlines in the top and bottom rows of the figure). The middle row shows two stimulus shapes – a concave C shape in column (a) and an ellipse in column (b). Note that the shape in (a) is darker and has a greater contrast with the white background, leading to higher activation per unit area of a neuron’s receptive field. Thus the degree of

activation of the two neurons in the third row can be approximately the same. Localization is a different matter, however. The figure centroid is shown by two red cross symbols, +, whereas the centers of the two neurons’ receptive fields are indicated by blue crosses. Localization is poor in case (a). The teardrop model of Layton et al. (2014) offers an inter-areal network to resolve figure localization in cases like in (a). Note that the areas chosen for investigation in the study described in Fig. 4 are also “C-shaped,” where the C is a block shape with right-angle corners

approach introduced the idea of cooperation and competition among representations in multiple cortical areas as a key requirement of figure-ground segregation.

A contrasting approach to modeling figure-ground segregation is taken by Kogo et al. (2010), who view figure-ground perception as a nonlinear differentiation/integration process that simultaneously accounts for border-ownership, lightness, and depth perception. A crucial step in this model is called “Integration for Surface Completion,” where estimates of depth

in a featurally homogeneous region’s interior are “filled-in” through values that are computationally propagated from signals from the region’s edges. This integration step differs with the Layton et al. 2014 approach, which depends on estimates of depth from multiple receptive fields in a higher visual area whose centroids are distributed (“jittered”) across the region’s area. Integration is a computation that would seem to “naturally” occur within a visual area, and further investigation of comparisons between classes of models employing integration versus inter-areal

feedback is needed to better understand figure-ground segregation.

Neural Responses to Texture-Defined Static Figures

Lamme (1995) is an important monkey single-unit recording study involving displays in which a figure-ground segregation is easily perceived (by humans) through differences in the orientation of texture elements. Although the receptive field of certain neurons in early visual areas of monkey lies entirely within the “figure” texture region, the neurons exhibit an enhanced firing rate compared to when the monkeys were presented a display containing a uniform texture of the neuron’s preferred orientation throughout the display.

The interior enhancement effect persists when the edges of the square are 8–10° and the modulation occurs after an 80–100 ms latency from the onset of the stimulus, which suggests *feedback from neurons with larger RFs* may be involved. A temporal analysis indicates that neural activity related to the edges of the figure emerges first, following a short latency, then interior enhancement occurs in the “late component” of the response (Roelfsema et al. 2002). A neuron that shows interior enhancement continues to fire at an elevated rate when the RF is centered at different positions within the texture-defined figure, and the firing rate drops when the RF is centered on the background. Neurons in V2 demonstrate a greater degree of interior enhancement compared to those in V1, and the magnitude of interior enhancement response is greatest in V4.

Motion-Based Figure-Ground Segregation

Fishes, frogs, moths, and snakes demonstrate adaptations in the appearance of their body to hide from predators. Through camouflage, the markings on the prey’s body cause the animal to be grouped with, rather than stand out from the surrounding. This strategy is effective as long as the animal *does not move*, because many predators and humans cannot easily detect stationary objects that resemble their surroundings in texture, color, and luminance. However, when a previously invisible animal breaks camouflage by sudden motion, humans rapidly perceive a figure

at a different depth from the surroundings, even if the texture is statistically identical. When a figure moves in front of a similarly textured background, it is said to produce kinetic occlusion (Gibson et al. 1969; Kaplan 1969). No reliable luminance contrast exists between the figure and background; there is only the relative motion between the texture patterns separated by a kinetically defined edge (kinetic edge). How do humans perceive the figure at a different depth than the background (figure-ground segregation), despite the figure and background possessing patterns with statistically identical luminance? Obviously, this is a demanding scene processing task for the primate visual system, which goes beyond simple contrast processing and is likely to involve brain areas involved in motion processing (the middle temporal area, MT, among others) as well as form processing (including V4 and probably other visual areas) to extract the moving form from visual motion cues scattered within the camouflaged scene. In this regard Layton and Yazdanbakhsh (2015) have suggested an interconnected network model of areas V1-V2-V4-MT, in which MT and V4, both monosynaptically connected to V2, process the motion and form signals, respectively. Another possible approach to motion-based figure-ground segregation is described by Barnes and Mingolla (2013), whereby motion onset and offset signals generated by accretion or deletion of texture elements via occlusion act as key gating signals for figure-ground segregation. Note that it is quite possible that the primate visual system has evolved multiple mechanisms, with partially overlapping competencies, to address the important needs of figure-ground segregation.

Need for Feedback Among Brain Areas

As noted in “the section [Temporal Dynamics of Border Ownership Neural Response](#)”, the primate visual system can rapidly recruit several cortical areas in the service of determining figure-ground relations. One way to investigate the mechanisms underlying the context-sensitive aspects of perceptual organization is the use of images that create bistable perception in which the perceptual interpretations of the image keep alternating over

time, while the physical input image is kept constant. One of the most famous images to induce perceptual bistability involving figure-ground organization is Rubin's "face-or-vase" image (Fig. 1b–c): The perceptual interpretation keeps alternating between "two faces" on the sides and a "vase" in the center, while the competing area is perceived as a part of the background. Because the perceptual switch in this case is specifically linked to the reversal of the figure-ground organization, we can call this phenomenon bistable figure-ground organization. Rubin presented his dissertation in 1915, with one of the key points that when two neighboring fields share a border, one will be seen as figure against the other as the background and that the percept of a figure is dominated by one of the fields against the other sharing that border. Pitts et al. (2011) used a Rubin faces/vase display to investigate the dynamics of figure-ground processing via EEG with humans and found that reorganization (faces to vase or back) could occur on a timescale of 200 msec or less, which allows for signals to propagate both in feedforward and feedback directions across visual areas.

Another example of bistable images is the Necker cube (Fig. 6), in which the front side of the cube swings between the top and bottom squares. Similar to Rubin vase, such a perceptual bistability can well be temporally modulated by attention, i.e., with a bit of practice, one can "will"

Figure-Ground Segregation, Computational Neural Models of, Fig. 6 The Necker cube is a classic example of bistable figures. Sometimes the lower square appears in front and sometimes in the back. The switch is instantaneous, showing our visual brain exhausts possible 3D alternatives which result in the same 2D projection

the top or bottom square closer and vice versa at a given time. Similarly, in Rubin faces/vase case, one can make the face or vase the figure by attention at a time. Such demonstrations further support the claim that figure-ground perception is a complex process that involves both top-down and bottom-up interactions in the primate brain. The degree of facility of such voluntary attentional switches has been exploited as potential markers for progression of Parkinson's disease (Diaz et al. 2015a, b).

"2D" Versus "3D" Displays: Figure-Ground Segregation and Stereopsis

Depth and separating a figure from background are tightly linked. A figure is generally closer in depth than the background. This brings up the question whether a figure can be purely defined and segregated from a ground area by binocular depth, with no reliance on contrast differences along an edge. Béla Julesz in 1959 generated pairs of images with random dots for which, if were shown to each eye separately, a portion of dots (e.g., forming a square) was seen at a different depth from the rest (Julesz 1971). Note that figure-ground segregation is thereby achieved, with the resulting stereoscopic border being owned by the nearer figure region. Closing each of the eyes (or just looking at each half pair instead) vanishes the percept of the circle as a figure against its background (Fig. 7). This is an example of pure stereopsis involvement (and nothing more) in forming a figure against its background. Here again, similar to the animal in camouflage case, there is no simple contrast between the figure and its background, and the figure and its borders are depth based. Are there single-cell data available for such figure-ground segregation to be used for a neural modeling approach?

Von der Heydt et al. (2000) investigated the representation of stereoscopic surfaces and edges in monkey visual cortex and whether such neural responses carry information of the figure borders and surfaces. Two key points are discovered in their work: first, if a figure like a square is generated by random dot stereogram in which there is no first-order (contrast-based) edge, the V1 cells respond to the stereoscopically defined figure

Figure-Ground Segregation, Computational Neural Models of, Fig. 7 Random Dot Stereogram. Looking at each half-pair doesn't result in seeing a particular pattern, yet, if the left and right eyes see only the left and right half-pairs, respectively, a circle in the middle appears farther. This example shows that while there is no visual border in

each half-pair, additional cues can create a pattern with clear borders. Additional cues can be stereopsis (here), motion, or large scale grouping of figure elements. (Figure is adapted from https://commons.wikimedia.org/wiki/File:Mh_stereogramm_randomdot.png under Creative Commons Attribution-Share Alike 3.0 Unported)

surface rather than to its edges; second, V2 cells respond to the stereoscopically defined edges of the figure rather than to its surface.

Conclusion

For most naturally occurring scenes, figure-ground perception is a quick, automatic, seemingly effortless, and successful process, with certain naturally occurring static images or humanly engineered camouflage being notable exceptions. Even in cases of successful camouflage, however, our visual experience is often one of a figure-ground segregation – just not the segregation that camouflage is designed to hide. Indeed, it is difficult to engineer a visual display that does not support figure-ground organization, i.e., a *ganzfeld* – a completely homogeneous light field – or very shallow gradients of luminance throughout the visual field. In contrast, if existing neural models capable of figure-ground segregation were to be challenged with a wide gamut of natural scenes, all of today's models would suffer

multiple and systematic failures, because existing neural models have been designed for a very small subset of such scenes. The diversity of the cortical networks and associated computational strategies that of our visual system uses to perform figure-ground segregation is partially revealed by variety of visual illusions, but the known class of figure/ground illusions is a particularly small and non-representative subset of natural scenes. Given that our visual system performs figure-ground segregation with its all-neural machinery capable of doing many other visual processes, understanding the underlying neural processing underlying figure-ground segregation can be indeed a difficult undertaking. It is only in recent years that “border-ownership” has been considered a “feature” to the human visual system and hence worth of study through single-unit neural recording or brain imaging. Much remains to be done.

One of the characteristics of visual neurons is their receptive fields, which are derived from the rich connectivity between neurons in different visual areas. We have not reached a sufficiently detailed understanding of the spatial and temporal

characterization of neuronal networks that perform the sophisticated task of figure-ground segregation on the order of a few tens of milliseconds. Progress in neuroanatomy and connectomics increasingly is revealing the geometry of available connections in brain networks, but a functional understanding of physiology remains constrained by several factors. One is the inherent spatial and temporal limits of each recording modality, be it single or multiunit recording, EEG, MEG, fMRI, or other modality. Another factor is that the structures of current computational neural models are far simpler than their biological counterparts, as is a virtual requirement of any progressive attempts at model-building. A satisfactory level of understanding of figure-ground segregation awaits further integrated cycles of experimentation and model development.

Before closing, we note that this article has not touched on two topics that a reader might wonder about. The first is deep learning or deep convolutional networks. Recent successes of this class of modeling architectures in object recognition are impressive in their accuracy, outperforming humans in many tasks for which a sufficient database of accurately labeled exemplars has been compiled to train the artificial neural network. Such networks have also enjoyed increasing successes in boundary segmentation and semantic segmentation, in the latter case assigning each pixel in an image the name of a category (e.g., “grass,” “road,” “sky,” etc.) that most likely is its source in an imaged scene.

Accurately finding all boundaries in a scene or semantically labeling all pixels in an image is, however, almost the exact opposite of figure-ground segregation. Animals have not evolved with the luxury of virtually limitless computational power or billions of computing cycles to before interacting with objects in their world. As noted at the start of this article, the significance of human figure-ground segregation is intimately tied to the machinery of primate vision – trying to balance the fine resolution of the fovea with a wide field of view, creating the tradeoffs of eye movements and cortical magnification.

Our default mode of visual scanning is to focus on one object at a time for a few hundred milliseconds, taking in “at a glance,” or perhaps with a handful of saccades, the important characteristics of each “figure” that we scrutinize in turn. It is thus not reasonable to expect computational approaches that treat large images as translationally uniform arrays of pixels to be informative about human figure-ground segregation. With this said, any machine vision algorithm that is designed to specifically segment an image into two regions, with one completely surrounded by another, can be said to be addressing the figure-ground problem in some way. A particular relevant example is that of Sarti et al. (2000) which uses a “seed” location (analogous to a point of foveation) to drive completion of illusory boundaries through an algorithm that uses partial differential equations and level-set methods. Such approaches, however, can be better characterized as machine algorithms “inspired by” primate neuroscience than as computational models “of” primate visual function, which is the focus of the present article.

The other topic is neural synchrony, which has been proposed as a coding strategy underlying perceptual binding between disparate regions of the visual field (Wolf Singer 1999). Dong et al. 2008 have reported that synchrony depends on the border-ownership selectivity of the neuron pairs being recorded. Neural synchrony has become a bit of a “field unto itself,” with controversies about methods and meaning of results that are not at all related to figure-ground perception. Moreover, even if it were conclusively shown that, during figure-ground perception, neurons coding a figure fire synchronously while those coding the ground fire in anti-phase with the neurons coding the figure but in synchrony with each other, a key question would remain: How did each member of each population get recruited to fire when it did, as opposed to some other time? In other words, what functional receptive field properties underlie the “sorting” of parts of the visual field into figure and ground? This article has focused on the latter questions.

Definition

Hypokinetic motor symptoms of Parkinson's disease are associated with elevated synchronization of neural oscillations in the beta frequency band. This synchronization is intermittent and exhibits specific temporal patterning. The properties of the

fine temporal structure of this synchrony may help to understand the mechanisms behind pathological neurophysiology of Parkinson's disease and assist in the development of adaptive brain stimulation techniques to suppress pathological neural activity.

Detailed Description

Neural oscillations and synchrony are believed to be important for various physiological and pathological phenomena in the brain (Buzsáki and Draguhn 2004; Colgin 2011; Fell and Axmacher 2011; Buzsáki and Schomburg 2015; Fries 2015; Harris and Gordon 2015) and have been extensively studied by using approaches and methods of computational neuroscience. Excessively strong or weak synchrony and oscillations of neuronal activities are presumably related to several motor and cognitive disorders (e.g., Schnitzler and Gross 2005; Uhlhaas and Singer 2006; Hammond et al. 2007; Oswal et al. 2013; Pittman-Polletta et al. 2015; Spellman and Gordon 2015), one of the prominent examples being Parkinson's disease.

Synchrony of Neural Oscillations in Parkinson's Disease

Parkinson's disease is a major neurological disorder characterized by degeneration of midbrain dopaminergic neurons resulting in a set of movement-related symptoms as well as other symptoms. The hallmark of Parkinson's disease is overall slowness of movement. This slow, hypokinetic behavior involves bradykinesia, akinesia, and rigidity (slowness of ongoing movement, slowness of movement initiation, and stiffness of joints). The etiology of Parkinson's disease is still a challenging question and perhaps involves different mechanisms outside of the basal ganglia. Nevertheless, the midbrain dopamine deficiency and accompanying slowness of movement are associated with excessive synchrony of neural oscillations in the basal ganglia (as well as the cortex, a major input to the basal ganglia) in the beta frequency band, usually

defined as 13–30 Hz (Brown 2003; Hammond et al. 2007; Bogacz 2014).

There are different views regarding the origin of the basal ganglia beta oscillations (local, cortical, striatal, or a mixture of all of them), the way how they mediate the movement, and whether they are in a direct causal connection with motor symptoms of Parkinson's disease. However, excessive beta oscillations and synchrony within the basal ganglia and between the basal ganglia and the cortex are observed in Parkinson's disease patients (Marsden et al. 2001; Cassidy et al. 2002; Fogelson et al. 2005; Hirschmann et al. 2011; Litvak et al. 2011; Ahn et al. 2015) and animal models of Parkinson's disease (Sharott et al. 2005; Mallet et al. 2008; Stein and Bar-Gad 2013). The level of synchrony and the power of beta oscillations are changed during movement and movement-related tasks (Cassidy et al. 2002; Levy et al. 2002; Brown 2003; Amirnovin et al. 2004; Kühn et al. 2004; Williams et al. 2005) and are reduced by treatments such as levodopa or deep brain stimulation in subthalamic nucleus (STN) (Silberstein et al. 2005; Stoffers et al. 2008).

Temporal Patterning of Synchronized Activity

The studies (such as discussed above) report elevated yet still moderate synchrony strength at rest. Thus, elevated synchrony in Parkinson's disease is not perfect (at least it does not stay perfect for prolonged intervals of time). This means the synchrony is stronger for some intervals of time and weaker (or nonexistent) for other intervals of time. It exhibits temporal variations changing from potentially very high to very low levels or from synchronized to desynchronized states. Even though it may average into some moderate synchrony strength overall, few long intervals of synchronized activity may be functionally different from many short synchronized episodes. In other words, different temporal patterns of neural synchrony may be related to different symptoms or conditions of the brain.

Synchronization of oscillations is a phenomenon which is not local in time and implies repetitive coordination of dynamics of coupled oscillators. There are multiple ways to define it

in mathematical terms (e.g., Pikovsky et al. 2001). It may be impossible to claim that signals or oscillators are synchronized at a particular time instant. However, it is possible to consider the synchronization, for example, measured as a phase-locking strength, over relatively short sliding time windows (especially if one can estimate the statistical significance of the phase-locking measured in this way). Moreover, recent time series analysis developments lead to a way of detecting whether the signals are in synch at each cycle of oscillations, provided there is overall statistically significant level of synchrony (Ahn et al. 2011; Rubchinsky et al. 2014). This approach considers time windows of intermittently synchronized activity to reconstruct the synchronized state from the data. Then, it is possible to check if the oscillations are close to this synchronized state or not at each cycle of oscillations. Statistic of distributions of durations of synchronized and desynchronized episodes reconstructed in this way provides a quantitative description of how synchronous dynamics is patterned in time (Ahn et al. 2011; Rubchinsky et al. 2014).

Temporal Patterns of Neural Synchrony Observed in Parkinsonian Patients

Application of this time series analysis approach to the recordings from the basal ganglia of patients with Parkinson's disease revealed high degree of temporal variability of neural synchrony in the beta frequency band (the references above regarding synchronization and oscillations in Parkinson's disease point to the association of beta-band activity, low dopamine status, and hypokinetic motor symptoms). The analysis of the phase-locking strength over a sliding time window of short length (about 1 s long, that is, about 20 cycles of oscillations) shows substantial variability of synchronization strength, which is going above and below significance level (Rubchinsky et al. 2012), where the latter was computed via phase-randomized surrogates (Hurtado et al. 2004), Fig. 1.

Each point at the graphs in Fig. 1 is not an "instantaneous" phase-locking strength; rather it represents phase-locking strength over a

Fine Temporal Structure of Synchronization of Neural Oscillations in the Basal Ganglia in Parkinson's Disease, Fig. 1 Dynamics of synchronous activity in the basal ganglia in a parkinsonian patient. Black line is the

phase-locking strength computed over a time window of 1 s (a) and 1.5 s (b). The gray line is the 95% significance level computed with phase-randomized surrogate data. (See the details of the analysis in Rubchinsky et al. 2012)

preceding time window involving tens of oscillatory cycles. It is possible to further improve the temporal resolution (although with some limitations) by adopting a different approach to analysis of the time series. Taking a very long time window, one can find out if there is some (statistically significant) strength of the phase-locking. This essentially provides a description of the synchronized state (the existence of certain preferred phase lag between the signals). Then, at each cycle of oscillations, one can detect if the oscillations are close to this synchronized state (then the signals are synchronized) or not close (then the signals are desynchronized). A way to formalize this approach is described in Ahn et al. (2011) and Rubchinsky et al. (2014). Going from observables to the phase space, this approach looks at whether the system of coupled oscillators is close to a synchronization manifold or not. Then one can measure the statistics of synchronized and desynchronized intervals leading to a description of variation of synchrony on very short time scales.

Analysis of microelectrode recordings from STN and internal globus pallidus (GPi) in parkinsonian patients provided a quantification of this

variability (Park et al. 2010; Ratnadurai-Giridharan et al. 2016). The distribution of durations of desynchronized events has a characteristic decaying form and is statistically similar for different locations in the parkinsonian basal ganglia (Fig. 2).

Furthermore, properties of the distributions of the desynchronization durations are correlated with the dopaminergic medication-induced improvements in the motor activity in parkinsonian patients (Ahn et al. 2018), pointing to its potential relevance to parkinsonian motor symptoms. Other studies indicate that transient synchrony states affect the motor performance in parkinsonian patients (Tinkhauser et al. 2020). Thus, the temporal evolution of cortical and basal ganglia synchronization rather than its time-average values may be critical for the parkinsonian neurophysiology (Cagnan et al. 2019).

Also, it is worth noting that parkinsonian tremor, while being distinct from hypokinetic symptoms in presentation and in mechanisms, also exhibits specific temporal patterning of synchronization with tremor-related neural activity in the basal ganglia (Hurtado et al. 2005).

Fine Temporal Structure of Synchronization of Neural Oscillations in the Basal Ganglia in Parkinson's Disease,

Fig. 2 Distribution of the durations of desynchronizations between spiking units and LFPs from the subthalamic nucleus of PD patients at the beta frequency band. Duration is measured in the number of cycles of oscillations. (See the details of the analysis in Rubchinsky et al. 2012)

Computational Modeling of the Mechanisms of the Intermittent Synchrony in Parkinsonian Basal Ganglia

There may be several potential factors behind the intermittent synchrony of neural oscillations. For example, the oscillations may go in and out of synchronized state because of noise (synaptic noise, channel noise, noisy inputs, etc.), fluctuations of coupling strength (synaptic plasticity), or insufficient synaptic coupling strength (strong enough to promote some degree of synchrony, but not strong enough to completely stabilize synchronized state). The episodic nature of the oscillations (which may be a generic phenomenon, Jones 2016) may, of course, be a factor too.

Simulations of conductance-based models of subthalamo-pallidal network of the basal ganglia suggested that the moderately elevated (due to the lack of the dopamine) synaptic strength of some dopamine-modulated synapses may lead to the synchronized dynamics with temporal patterns similar to those in the experiments (Park et al. 2011). Computational modeling of the parkinsonian basal ganglia is a complex field of research with multiple and sometimes contradictory models (Rubin 2017), of which these numerical studies are not an exception. However, they

compared not only the average synchrony strength but also the rates of transitions between synchronized and desynchronized states, thus comparing the structure of the phase space of the experimental system and that of the model. Further modeling indicates that dopaminergic degeneration-induced changes in the cellular properties of the basal ganglia cells may work cooperatively with this phenomenon (Park and Rubchinsky 2012) and the beta-band activity coming from the cortex may further facilitate synchronized beta oscillations locally generated in the subthalamo-pallidal circuits (Ahn et al. 2016).

An interesting observation of these modeling studies (Park et al. 2011) was that the dynamics with the realistically patterned synchronized oscillations is located (in the space of parameters) on the border of the synchronized and desynchronized dynamics. Therefore, the highly variable evolution of neural synchrony in the basal ganglia in Parkinson's disease may be indicative of the propensity of these brain circuits to express the transient episodes of synchronized beta-band activity, which is a physiological phenomenon in the healthy state (Engel and Fries 2010). The pathological low-dopamine state

would present itself in the network, which is more strongly connected than the healthy one and exhibits ongoing intermittent synchrony instead of the functional ability to generate brief episodic synchronous dynamics only when needed (Park et al. 2011; Rubchinsky et al. 2012).

Intermittent Oscillations and Synchrony in Parkinson's Disease and Adaptive Deep Brain Stimulation

One of the techniques to treat the symptoms of Parkinson's disease is deep brain stimulation (DBS). DBS delivers electrical stimulation to subcortical brain areas via implanted electrodes. In the case of Parkinson's disease, the targets include STN and GPi (Wichmann and DeLong 2006; Kringsbach et al. 2007). The conventional DBS delivers relatively high-intensity current, and experimental evidence suggests that it may work by suppressing oscillations and/or synchronization of neural activity in the beta band (e.g., Wingeier et al. 2006; Kühn et al. 2008). This naturally brings the issue of using stimulation only when oscillations or synchrony is relatively strong, that is, using stimulation adaptively as a control tool (see, for example, Schiff 2012). Some approaches of adaptive DBS have been tested clinically, yielding promising results (e.g., Little et al. 2016). Understanding the nature of the intermittently synchronized oscillatory neural activity in the parkinsonian basal ganglia and its relation to parkinsonian motor symptoms may facilitate the model-based development of more efficient adaptive DBS strategies.

Definition

Finite element modeling is an important computational tool in neural engineering to simulate neural excitation with implanted electrodes or with surface electrodes. Besides its importance for analyzing artificially generated neural activities, e.g., in the spinal cord (reference to entries

► “Finite Element Models of Transcutaneous Spinal Cord Stimulation” and ► “Paraspinal Magnetic and Transcutaneous Electrical Stimulation”), this technique is useful to interpret recorded electrical biosignals generated by neural or muscle tissue activities.

Detailed Description

Neural signals propagate as transmembrane voltage along neural structures, and thereby they cause plenty of tiny currents in any active region of the nervous system. Our understanding of neural activity by means of electrode recordings, e.g., at the surfaces of the skull (EEG), the cortex (ECoG), or intracortically with microelectrodes, is supported by modeling studies that take care of the electrical properties of the biological tissue. Important elements for such studies are the transmembrane currents which act as spatially distributed current sources, the conducting volume, and its electrical properties (Wolters et al. 2006; Zhang et al. 2006).

Extracellular electrical stimulation of the neural tissue is another important field of computational neurosciences with increasing impact in neurophysiology, neural engineering, and clinical applications (Rattay 1999; Rattay et al. 2000, 2001; Kunzel and Grill 2004; Oozeer et al. 2005; Butson et al. 2007; Ahuja et al. 2008; Stickler et al. 2009; Ladenbauer et al. 2010; Mou et al. 2012; Lai et al. 2012). A third field of interest in finite element modeling (FEM) of volume conductors is the ephaptic coupling of neural structures, that is, the influence of active membranes on the excitability of neighbored cells (Jönsson et al. 2008; Anastassiou et al. 2010).

The calculation of the electrical potential Φ in the volume conductor is based on a reduced form of Maxwell's equation which reads as

$$\nabla \cdot \left(\sigma \nabla \Phi + \epsilon \nabla \frac{\partial \Phi}{\partial t} \right) = 0 \quad (1)$$

where σ is the conductivity and ϵ is the permittivity of the medium. In many applications, neural

activities are simulated with compartment models where the transmembrane voltage V is the difference between intra- and extracellular potential, that is, $V = V_i - V_e$. Usually V is calculated with a set of differential equations of Hodgkin-Huxley type (McNeal 1976; Rattay 1990; Mainen et al. 1995; Rattay et al. 2002; Kuhn et al. 2009; Hu et al. 2009).

External Neuronal Stimulation

Most stimulation modeling studies neglect the secondary influence of the transmembrane currents of excited structures on the electrical field generated by the stimulating electrodes. For more accurate modeling see, e.g., Altman and Plonsey (1990) or Martinek et al. (2008). In the first modeling step, the excitable structures are not involved, and the electrical field is calculated with FEM or, for simple geometries, with analytical methods. During stimulation, e.g., the application of square pulses, electrode potentials are the driving elements. As intracellular current flow is not included in this first step, Φ is replaced by the extracellular potential V_e in Eq. 1:

$$\nabla \cdot \left(\sigma \nabla V_e + \epsilon \nabla \frac{\partial V_e}{\partial t} \right) = 0 \quad (2)$$

In order to reduce the computational effort, the minor contribution of the second term in Eq. 2 is often ignored resulting in the quasistatic approach with $\epsilon = 0$. However, investigations of forearm stimulation demonstrated the importance to incorporate tissue capacitance for voltage-regulated transcutaneous stimulation. As consequence of the high skin capacitance, the extracellular potential at the nerve significantly dropped during the applied course of the pulse (Kuhn et al. 2009). In cases of implanted electrodes, the quasistatic approach deviated less than 6% in comparison with the full solution of Eq. 2. Nevertheless, the electrode tissue interface may cause quite different voltage profiles for current- or voltage-controlled stimulation (Miocinovic et al. 2009; Goo et al. 2011).

Second Spatial Derivative of V_e and Current Density Are Used to Predict Regions of Spike Initiation

The goal of many volume conductor studies is the analysis of stimulus-recruitment relations. A common question, e.g., in deep brain stimulation, is as follows: What is the volume of neural tissue activated? The key point of this section is how the FEM output in the region of interest can be used in the second evaluation step for a recruitment analysis of the stimulated tissue. Several criteria are discussed in the following.

Current density criterion. A simple answer for step two comes from the Hodgkin-Huxley formulation where transmembrane currents are computed for 1 cm² of the axon membrane, and, consequently, the physical unit of the stimulus is also current density. With this fact in mind, one can assume that spike initiation occurs within a volume around the electrode where current density exceeds a threshold value. In an infinite homogeneous medium, a monopolar spherical electrode causes current densities proportional to $1/r^2$, where r is the distance from the center of the electrode to the point of interest. In other words, in this simplest approach, spike initiation at distance r demands for electrode currents proportional to r^2 . Interestingly, a quite linear relationship between electrical conductivity data and data from diffusion tensor MRI (DTI) of human brain regions (Tuch et al. 2001) demonstrated essential variations in the direction-dependent conductivity. This relationship allows an improvement in simulating the activated volumes in comparison with the spherical borders of the simplest approach. Thus, the borders of activation can be replaced by patient-specific surfaces based on FEM that combine the body and electrode geometry data with DTI (Butson et al. 2007).

The morphometric and electrical cell data is often disregarded in FEM analysis due to the variety in tissue shapes and other details not available in the living human brain, and this is a great

limitation. From extraneural peripheral nerve stimulation, it is known that thick fibers are recruited easier than thinner ones. This phenomenon is called reverse recruitment order as it reverses the natural recruitment sequence (Blair and Erlanger 1933). This phenomenon is an example that demonstrates the weakness of simple approaches which ignores all the electrical properties of nerve cells but uses current density or any other parameter of the volume conductor as recruitment criterion.

Threshold voltage criteria. Several of the early FEM studies published the potential distribution in the body part of interest when stimulated with surface or implanted electrodes. Guided by the threshold voltage hypothesis – an action potential is initiated as soon as the membrane voltage exceeds a value of about 20 mV above the resting state – they had no simple method to define a threshold value for the external potential. Another approach is based on a threshold value for the electrical

field (Kasi et al. 2011). Quite different electrode currents are obviously calculated for the same neural stimulation task depending on the evaluation criteria as the iso-contours of current density, electrical potential, and electrical field are not the same.

Activating Function Criterion

Many modelers prefer a two-step method in order to compute responses of excitable cells to electrical stimulation. In the first step, the electrical field in the volume conductor is calculated. In the second step, a compartment model of a target cell is evaluated. This method is computationally extensive, but it shows the complete spatial and temporal excitation and conduction process of a cell for a given electrode situation. A compartment model is a network of resistances and capacitances, where the current to the center of compartment n consists of the following components: a capacitive current, ion currents across the membrane, and intracellular currents to neighbored compartments. Current flow in compartment n results in

$$\frac{dV}{dt} = \left[-I_{ion,n} + \frac{V_{n-1} - V_n}{R_{n-1}/2 + R_n/2} + \frac{V_{n+1} - V_n}{R_{n+1}/2 + R_n/2} + \frac{V_{en-1} - V_{en}}{R_{n-1}/2 + R_n/2} + \frac{V_{en+1} - V_{en}}{R_{n+1}/2 + R_n/2} / C_n \right] \quad (3)$$

with transmembrane potential V , ion current I_{ion} , axial resistance R , and membrane capacity C . The direct stimulating influence of the extracellular potential on compartment n is defined by the activating function f (Rattay 1999) which is the driving term of the differential Eq. 3:

$$f_n = \left[\frac{V_{e,n-1} - V_{e,n}}{R_{n-1}/2 + R_n/2} + \frac{V_{e,n+1} - V_{e,n}}{R_{n+1}/2 + R_n/2} / C_n \right] \quad (4)$$

For a fiber with constant diameter d , constant compartment length Δx , intracellular resistivity r_i , and specific capacity c , Eq. 4 is reduced to

$$f_n = \frac{d}{4c\rho_i} \cdot p \frac{V_{en-1} - 2V_{en} + V_{en+1}}{\Delta x^2}. \quad (5)$$

All terms within the brackets of Eqs. 3 and 4 are currents. Therefore, neglecting the weighting factor $1/C$, the stimulating influence of the activating function f can be interpreted as an injected virtual current in every compartment. In regions where this current is positive, the membrane depolarizes, and where it is negative, it tends to hyperpolarize. For the case of a long straight excitable fiber (axon, dendrite, or muscle fiber) with constant diameter, Fig. 1 explains the activating function concept for cathodic stimulation on the basis of virtual current injection. Note that the second term on the right side of Eq. 5 is the second difference quotient of the extracellular potential along the fiber. With $\Delta x \rightarrow 0$, f becomes proportional to the second derivative of V_e , and therefore $d^2 V_e / dx^2 > 0$ indicates the regions for spike initiation.

Finite Element Modeling for Extracellular Stimulation, Fig. 1 Extracellular stimulation of a straight unmyelinated axon with a small spherical electrode. (a) Geometry and isopotentials, simulated for an equivalent point source $50 \mu\text{m}$ above a fiber positioned at the x-axis. (b) Extracellular potential $V_e = \rho_e I_{el} / 4\pi r$ with $r = \sqrt{(x - x_{el})^2 + z_{el}^2}$ is used to calculate the activating function. (c) A fiber with $d = 1 \mu\text{m}$ and compartment length $\Delta x = 10 \mu\text{m}$ results in a peak activating function value of 740 mV/ms . According to Eq. 5, this is the slope of the membrane voltage in the compartment below the electrode at the beginning of the $-25 \mu\text{A}$ pulse. According to Eq. 4, the virtual currents are $f_n C_n$. With $C_n = d\pi\Delta x c = 3.14159 \times 10^{-7} \mu\text{F/cm}^2$ and specific membrane capacity $c = 1 \mu\text{F/cm}^2$, the maximum injected current is 232 pA at the center of the activated region. As the length of the activated region ($1.414 \cdot z_{el}$) is defined by an angle of 70° (Rattay 1986), this region increases in a linear way with the electrode distance. (d) Vertically shifted transmembrane voltage profiles in time steps of $200 \mu\text{s}$. The first response of the neuron at the beginning of the stimulus pulse is proportional to the activating function shown in C: hyperpolarized and depolarized regions in green and red, respectively

Finite Element Modeling for Extracellular Stimulation, Fig. 2 Hyperpolarized (green) and depolarized (red) regions of a stimulated axon (left) and voltage profiles as functions of time for the compartment model shown in Fig. 1 (right). Every line shows the transmembrane voltage of a compartment as function of time with a vertical shift according to the position of the compartment. The axon is for $100 \mu\text{s}$ in the resting state before it is stimulated with a cathodic $100 \mu\text{s}$ pulse as in Fig. 1d. The compartment closest to the cathodic electrode has the largest activating function value, and it is the spike initiation site (thick red line). As predicted by Fig. 1c, the largest slope in the red region ($f > 0$) is about four times the value of the largest green slope indicated by the green arrow. Therefore, a change of stimulus polarity needs about four times larger electrode threshold currents. This theoretical result for extracellular axon stimulation (Rattay 1986) is in accordance with experimental observations (Ranck 1975)

We assume that the axon is at rest before a stimulus is applied (Fig. 2). During this resting phase, the sum of the first three terms at the right side of Eq. 3 is zero, and consequently the activating function quantifies the slope of membrane voltage at stimulus onset in every compartment. The activating function is the rate of transmembrane voltage change and it has the unit mV/ms . Note that the activating function predicts the reverse recruitment order phenomenon as the scaling factor of f is proportional to fiber diameter d (Eq. 5).

Stimulus Threshold Current Depends Also on Type and Densities of Ion Channels

The activating function concept is an essentially better predictor for spike initiation than all the other methods presented at the beginning of the last section. The activating function is a fascinating concept because of its simplicity to predict regions of excitation in a target neuron without

Finite Element Modeling for Extracellular Stimulation, Fig. 3 Cathodic microelectrode stimulation at the dendrite of a rectified pyramidal cell. **(a)** The non-branching model cell consists of the following functionally different segments: dendrite, soma, axon initial segment (AIS), unmyelinated axon, myelinated axon with active membranes in the nodes of Ranvier (NR), and an unmyelinated terminal. **(b)** Two types of sodium channels enable initiation and conduction of spikes. High-threshold Nav1.2 channel densities represented by the maximum conductance (*magenta*) exist in the upper part of the neuron until AIS and low-threshold Nav1.6 channels (*purple*) from AIS until the axon terminal. Note that high concentrations from axon hillock until myelination exceed even that of nodes of Ranvier by a factor 2, whereas in soma and dendrite, a

uniform maximum sodium conductance of 8 mS/cm² is assumed (Hu et al. 2009). **(c)** Transmembrane voltages as functions of time. Electrode tip is assumed 300 μm from the soma and 80 μm from the axis ($x_{el} = 300 \mu\text{m}$, $z_{el} = 80 \mu\text{m}$) in a homogeneous medium with resistivity $\rho_e = 300 \Omega \cdot \text{cm}$. At this distance the electrical field has a direct depolarizing effect only within the gray-shaded region where the slopes at stimulus onset in **(c)** are positive. Spike is initiated in the compartment closest to the electrode (*red*) and propagates in both directions. When intracellular currents cross the soma (*cyan*), they activate the low-threshold regions in the axon, and therefore action potential peaks appear earlier in these axon compartments than in the soma and the last presomatic dendritic compartments

using knowledge about the ion channel compositions of the excitable membranes. However, simulating the gating processes of the cell membrane is needed for further improvements of cell response prediction.

The important impact of ion channel compositions in the functionally different segments of a stimulated neuron is demonstrated with the following examples. In order to reduce geometric influences, microelectrode stimulation of a cortical pyramidal cell is simulated by a non-branching rectified model cell. Ion channel gating dynamics and more details about electrical and geometrical data are given in Rattay and Wenger (2010). Even the low density of high-threshold sodium channels (Nav1.2) enables a conducted spike to be

initiated within the dendrite (Fig. 3). For this electrode position close to the dendrite, the positive values of the activating function are found within a small region in the dendrite as predicted by the 70° limit shown in Fig. 1. An interesting phenomenon appears when the dendrite is passive or also when the sodium channel density is reduced in the modeled neuron below a critical value needed for action potential conductance. In such cases where the stimulating microelectrode is in front of the soma, the neuron is not excitable with negative pulses. This phenomenon becomes effective for the model assumptions when the electrode-dendrite distance is reduced because current influx within a shortened active zone (defined by the 70° borders, Fig. 1) cannot excite

the neighboring hyperpolarized regions. Surprisingly, this failure effect is more pronounced for thicker fibers. This is in contrast to the reverse recruitment order for excitable fibers. For details see Rattay and Wenger (2010).

In the next example, the electrode is moved in constant distance along the axis of the neuron. Several phenomena can be observed (Fig. 4a). (i) The distal end of the axonal initial segment with high Nav1.6 channel density is very sensitive to cathodic stimulation, and this is a preferred site of spike initiation. (ii) The neuron is even more excitable at the third and fourth nodes of Ranvier despite the essentially lower ion channel densities. It is a general property that myelinated axons are easier to excite than unmyelinated ones which is a consequence of higher activating function values in nodes of Ranvier that are favored by the properties of the internodes (Rattay 1986, 1990, 1999). (iii) Moving the electrode along the thick dendrite in a distance of 100 μm from the neuron axis

needs about twice the threshold current in comparison to the positions along the axon. (iv) The thresholds in 50 μm distance are higher as expected according to the prediction of the quadratic rule proposed in the literature (Stoney et al. 1968; Tehovnik et al. 2006; Butson et al. 2007), shown by dashed blue line in Fig. 4a and by Fig. 4b. (v) Electrodes above the center of an internode need doubled threshold currents compared to positions above a node of Ranvier. This node-internode threshold relation known from peripheral nerve stimulation becomes more and more pronounced when electrode-fiber distance is reduced (Rattay 1987). (vi) Within a dendritic region ($-149 \mu\text{m} < x_{el} < -37 \mu\text{m}$), anodic threshold is lower than cathodic which is in agreement with experiments (Ranck 1975) and theory (Rattay 1999). (vii) Anodic threshold current of the 5 μm diameter dendrite example increases in an exponential way with distance from the soma (comp. the rather linear relation of the left part of

Finite Element Modeling for Extracellular Stimulation, Fig. 4 Threshold current as a function of electrode position for monophasic 100 μs pulses for the model neuron of Fig. 3. (a) When the microelectrode tip is moved from left to right in constant 100 μm distance to the neuron axis, cathodic threshold current (red line, marked as I_{100}) is rather constant along the dendrite, but threshold decreases quickly before arriving at the soma ($x_{el} = 0$) with a local minimum at the distal end of the AIS (AIS is marked as gray region). The zigzag line demonstrates low thresholds when the electrode is just above a node of Ranvier. For half the axial distance ($z_{el} = 50 \mu\text{m}$), cathodic threshold (blue line) is similar in shape with the broken blue line which is the prediction for a quadratic current distance rule ($I_{100}/4$ is

a vertical shift of the red I_{100} line, corresponding to the factor 1/4 of the logarithmic scale). However, two discrepancies are characteristic: full blue line values are always higher and, second, the threshold ratio for nodal and internodal positions is increased. Anodic stimulation (green line) does neither favor positions above nodes nor the vicinity of the AIS. Thin green and blue lines show threshold predictions when the dendritic diameter is reduced from 5 to 1.25 μm . (b) Radial current distance relations for three selected positions as marked in (a): middendritic, soma, and distal end of AIS. Indicated by the slopes of the gray arrows, in all three cases, there is a clear trend from a linear to a quadratic relation when electrode distance is increased in radial direction

the green line in the logarithmic current scaling of Fig. 4a). The thin dendrite has another threshold characteristic as explained below. (viii) The extreme node-internode threshold fluctuations seen for cathodic pulses are lost when pulse polarity is reversed. (ix) In general thin dendrites have higher thresholds (comp. thin and thick green and blue lines in Fig. 4a).

Stimulation of the Lumbar Spinal Cord with Epidural Electrodes

In the following modeling example, we analyzed which neural elements are primarily excited in order to explain observations during human lumbar cord stimulation (Dimitrijevic et al. 1998; Minassian et al. 2007, ▶ “Paraspinal Magnetic and Transcutaneous Electrical Stimulation” in this encyclopedia). As described above, we used a two-step procedure for this task. In the first step, isopotentials are computed with finite element software ANSYS for a typical position of a bipolar electrode as implanted in paralyzed patients (Fig. 5). The stimulator (Itrel 3, model 7425, Medtronic) delivered continuous, non-patterned stimulation with 1–10 V at 2.2–130 Hz and asymmetric biphasic pulses with a 210 μ s main pulse and a long second pulse for avoiding charge accumulation. Because of its overlength, the influence of the second pulse can be neglected in this quasi-static approach, and all presented conclusions could be done with a single finite element evaluation.

The compartment models of the target neurons are based on the CRRSS (Chiu-Ritchie-Rogart-Stagg-Sweeney) model in the form described in Rattay (1990) and Rattay et al. (2002). The resulting differential equations were evaluated with software ACSL. Spike initiation points were also analyzed with the activating function concept.

The purpose of our investigations was to find which neural elements are the primarily excited ones. First ideas are guided by the general knowledge that myelinated fibers are easier to excite than the unmyelinated. Moreover, thick axons have lower thresholds than thin axons, a fact that

Finite Element Modeling for Extracellular Stimulation, Fig. 5 Potential distribution within the dural sac is computed with the finite element method for bipolar stimulation with an implanted electrode. The volume of interest has to be embedded into a larger volume in order to use appropriate boundary conditions, e.g., a cylindrical body segment (not shown, with no current flow components across the surface). Axons close to the cathode (*red potential lines*) are preferred targets for stimulation

is deduced from the weighting factor $d/4r_i c$ in Eq. 5. Therefore, the thick sensory afferents may be most sensitive to low stimuli. However, it could be that the thinner dorsal column fibers are even more sensitive as they may be closer to the electrode at the thoracic level. Such fibers are comparable in diameter and position with the vertical branches of our target neuron marked by red arrow in Fig. 6a.

The activating function concept shows two closely neighbored hot spots in the afferent

Finite Element Modeling for Extracellular Stimulation, Fig. 6 (a) Three-dimensional view of the lower spinal cord with a sensory fiber (within the posterior root, curved trajectory) and its axonal branches in the back side of the spinal cord (hatched area, vertical arrow) with a single synaptic connection to a motoneuron. Red arrows and red line indicate the hot spot for the spike initiation at the site where the posterior root fiber enters the spinal cord.

(b) Extracellular voltage generated by epidural stimulation, (c) activating function, and (d) membrane voltage for an S1 posterior root fiber stimulated 4% above the characteristic fiber threshold with a midsagittal electrode at L4 spinal cord level. Note that the positive part of the activating function is restricted to a single node of Ranvier (peak). In this hot spot an action potential is generated that propagates into the spinal cord and in antidromic direction

rootlet fibers: the regions with sharp curvature before the entry point in the spinal cord and the entry point itself where a sudden change of the electrical conductivity at the interface between two media supports the initiation of action potentials. Both cases result in large values of the second spatial derivative of V_e and thus of the activating function. Computer evaluations with the full system of differential equations demonstrated that with the applied stimulus intensities, spikes can typically be generated in rootlets which enter the spinal cord up to 2 cm below the level of the cathode, but there is no spike initiation in the dorsal columns in the case of lumbar stimulation.

Other candidates for spike initiation for epidurally placed lumbar spinal cord electrodes are the AIS of spinal interneurons and their myelinated axonal segments. A comparison with Fig. 4a shows that AIS excitation has about the same threshold as the nodes of Ranvier. As the axons of the interneurons are essentially thinner than that of the Ia afferents and even thinner than the dorsal column fibers, model interpretation

predicts significantly larger thresholds for interneurons than for thick axons in sensory rootlets.

Further details and related explanations are found in entries ► [“Paraspinal Magnetic and Transcutaneous Electrical Stimulation”](#) and ► [“Finite Element Models of Transcutaneous Spinal Cord Stimulation”](#)

Conclusions

Finite element evaluation of the electrical field is an important tool for modeling nerve stimulation. The most important question in this context is which of the FE output data should be used to quantify the recruitment order of the excitable tissue. In this entry, it was shown that current density is not a good indicator, but it is of value for a rough approach if no information is available about geometrical and electrical details of the involved neural structures. Better insights can be found from the activating function concept and from the compartment.

Spatial differences in ion channel compositions within a single neuron can cause surprising phenomena. Such phenomena can be detected when all differential equations of the compartment model of a target neuron are evaluated. On the other hand, some remarkable observations about spike initiation sites are based on geometric configurations that can be explained with FEM. An example is that hot spots in sensory afferents stimulated with implanted epidural lumbar cord electrodes can be the same when transcutaneous stimulation is applied (Ladenbauer et al. 2010; Danner et al. 2011; ► “Finite Element Models of Transcutaneous Spinal Cord Stimulation” in this encyclopedia). The effect is surprising as both the larger distance to the axon and the larger electrode size of the surface electrode suggest a poor focusing effect in comparison with the implanted electrodes.

Another surprising phenomenon which was recently discovered is the rather poor focal stimulation success with microelectrodes. Low-current stimulation produces a sparse and distributed set of activated cells often with distances of several hundred micrometers between the cell bodies and the microelectrode (Histed et al. 2009). A reasonable hypothesis to explain the sparsely distributed population of somas results from a computer simulation analysis based on a rather dense concentration of collaterals of many neurons in the close surrounding of the electrode tip. These thin axons and dendrites are capable of generating an ongoing nerve impulse or activating the distant AIS via intracellular current flow. Therefore, the cell bodies of stimulated cells can be situated within a distance of several hundred micrometers or more relative to the electrode tip, whereas most of the cell bodies closer to the electrode have a small probability to be activated (Rattay and Wenger 2010). A similar conclusion is reported concerning the spinal cord. Previous studies demonstrated that extracellular stimulation within the spinal cord activates fibers in passage at lower stimulus intensities than neuronal cell bodies (Renshaw 1940). Action potentials elicited in localized terminal branches of afferents

are assumed to spread antidromically to all terminal branches of the afferents and transsynaptically excite motoneurons and interneurons far away from the stimulation site (Gaunt et al. 2006).

Definition

Extracellular electrical neural stimulation consists in injecting a current through an electrode located in a neural tissue. A potential field is created in the tissue, which influences the membrane potential of neural elements. The membrane response depends on the shape of the potential field around the neuron, which depends itself on the electrode configuration. Finite element models (FEM) are numerical models that can be used to compute the potential field and predict the effect of a given electrode configuration. These models are based on a description of the geometry and the electrical properties of the conductive media and specific constraints on their boundaries.

Detailed Description

Electrical stimulation of neural tissues has been extensively used for decades. More recently, an increasing interest has grown to build neural prosthesis based on arrays of microelectrodes to restore functional activity in the damaged central nervous system. The fine use of electrical microstimulation requires prior analysis of how the potential field is generated in a tissue. The stimulating field generated by a given electrode configuration can be

calculated using FEM approaches (McIntyre and Grill 2001). For this purpose, different commercial software are available.

Building a FEM model requires the following steps:

1. Creating the geometry of the model comprising all the conductive volumes constituting the neural tissue and surroundings. The geometry of these volumes is meshed in 3D into elementary elements (e.g., tetrahedrons) on the vertices and edges of which the electrical potential is calculated.
2. Setting volume equations. Classically, each volume is considered homogenous with a conductivity value σ (e.g., $\sigma = 0.1 - 0.4$ S/m for the neural tissue – see (Ranck 1963; Ranck and Bement 1965)). Under the quasi-static approximation (Hamalainen et al. 1993), the equation governing the computation of the electrical potential V in this volume is the Laplace equation:

$$\nabla \cdot \sigma \nabla V = 0 \quad (1)$$

3. Setting boundary conditions between conductive volumes. At the boundary between two conductive volumes having different conductivities σ_1 and σ_2 , the normal component of the current density is conserved (Plonsey 1969), which can be represented by the following boundary equation:

$$\sigma_1 (\nabla V \cdot \mathbf{n})_1 = \sigma_2 (\nabla V \cdot \mathbf{n})_2. \quad (2)$$

4. Setting boundary conditions to insulating boundaries. Boundaries through which no current flows are represented by the homogenous Neumann boundary equation:

$$\sigma \nabla V \cdot \mathbf{n} = 0 \quad (3)$$

5. Setting boundary conditions on the surfaces of active electrodes. In order to correctly calculate the potential field V in the tissue, the electrode-tissue impedance can be explicitly incorporated into the boundary condition at the interface (Heuschkel et al. 2002). This

requires the use of the following Robin boundary condition (Joucla and Yvert 2009, 2012):

$$\sigma \nabla V \cdot \mathbf{n} = g \cdot (V_{\text{metal}} - V), \quad (4)$$

where g is the surface conductance of the electrode and V_{metal} is the voltage applied to the electrode. This equation, which takes into account the potential drop at the electrode-tissue interface, states that, at a given location on the electrode, the current flowing through the interface (left-hand side) is the product of the potential drop by the surface conductance of the interface (Ohm's law, right-hand side).

Once the model is built, the electrical potential V is calculated by solving Eq. 1 under the specified boundary conditions. It should be noted that the potential field only provides a first description of the effect of a stimulation. In particular, the neural response could further be calculated. This can be done by embedding a compartment neuron model into the stimulating field and computing the response of the membrane to the field (McIntyre and Grill 2002; Joucla and Yvert 2009). For such approach, the NEURON software environment can be used (Hines and Carnevale 1997). Alternatively, a whole finite element model can be built, in which the neuron is introduced in the model as a subsequent conductive volume on the surface of which the dynamical equations governing the membrane response are incorporated through dedicated boundary conditions under a thin film approximation (Joucla et al. 2014).

Definition

Transcutaneous spinal cord stimulation (SCS) is a noninvasive method to electrically stimulate afferent structures of the human lumbar spinal cord. These are the same neural targets as predominantly activated by epidural implants. Biophysical principles derived from computer simulations contributed to the identification of the directly activated neural structures. These simulations combine finite element (FE) models with nerve fiber models and the activating function concept. The transcutaneously generated electric field is inherently non-focal, and thus, nerve fiber activation relies on inhomogeneities of the volume conductor and the anatomical paths of the target fibers relative to the electric field. The anatomy, its electrical properties, and the neurogeometry cause localized low-threshold sites within the widespread field and allow for the observed selective stimulation. Computer simulations are crucial for understanding the neuromodulative effects of transcutaneous SCS resulting from the trans-synaptic activation of the spinal cord neural circuits and for further improving the stimulation technique.

Detailed Description

Epidural SCS involves the activation of neural target structures by leads placed in close distance of a few millimeters to the posterior aspect of the spinal cord. In transcutaneous SCS, the same deeply located neural structures are targeted from a distance of several centimeters from the body surface. Compared to the neural structures, the stimulating skin electrodes are large. Several anatomical structures between the electrodes and the spinal cord introduce electrical inhomogeneities and anisotropies, which in turn influence the generated electric potential. Yet, electrophysiological studies showed that transcutaneous SCS

reliably and selectively stimulates similar neural structures as with epidural electrodes, i.e., sensory fibers within the posterior roots and rootlets (Minassian et al. 2011).

Computer simulations that calculate the generated electric potential and its effect on neural structures are essential in understanding the immediate effects of SCS (Holsheimer 1998). The problem of calculating the electric potential distribution in a complex volume conductor can be mathematically formulated by partial differential equations. Due to the geometrical complexity and inhomogeneities of the anatomical structures, these equations are usually only tractable by applying numerical approximation methods such as the finite difference, FE, boundary element, or multigrid method (Johnson 1997).

Here, the application of the FE method is elaborated for the approximation of the produced electric potential while assuming quasi-stationary conditions (for details on the FE method, see elsewhere in this book, Rattay: Finite Element Model of Volume Conductor). A model is always an abstraction of the reality and can represent only rather simple anatomical properties, can model average dimensions, or can be tailored to an individual subject. Current models of transcutaneous SCS (Ladenbauer et al. 2010; Danner et al. 2011) cover a general case with a rather simple geometry.

As opposed to models of epidural SCS where most of the generated currents flow inside the spinal canal, the spine and its geometry are paramount for calculating the electric potential across the neural target structures produced by the skin electrodes. The simplified model must include anatomically realistic regions of the soft tissues in-between the bony structures with comparably high conductivities, thus allowing for current penetration of the canal. Structures below the electrode (i.e., the skin, subcutaneous fat, paraspinal muscles) and the spine, including the ligaments and intervertebral disks, are influencing the produced field near the target structures and thus need to be included in the model of transcutaneous SCS. Furthermore, the detailed anatomical properties of structures inside the spinal canal (e.g., the spinal cord gray and white matter, spinal nerves,

cerebrospinal fluid, epidural space) need to be modeled. Figure 1a, b illustrates the model geometry, Fig. 1c is a sketch of potential target fibers, and Fig. 1d shows computed current flow lines.

In a further step, the electric potential computed by the FE models is evaluated along determined paths, representing the geometry of potentially excitable neural structures. The excitability of nerve structures depends on several factors. The soma is hard to excite due to its relatively

high membrane capacitance (Rattay 1999). The activation thresholds of myelinated nerve fibers are lower than that of unmyelinated ones and are lower for nerve fibers of larger diameters (Ranck 1975). Thus, large-diameter myelinated axons can be preferentially selected for the simulation as target structures.

The stimulation effects on the target neural structures can be estimated from the activating function concept (Rattay 1999), which states that

the de- and hyperpolarization induced by an externally applied electric field is proportional to the second-order spatial differential of the electric potential (or the negative going, first-order differential of the electric field) along the nerve fiber. Thus, the spatial trajectory of the fibers relative to the field and the traversal of media of different conductivities greatly influence the excitability. Nerve fiber models can be used to identify the activation thresholds and simulate the influence of the fine structure of the neurons (esp. branchings and collaterals; Struijk et al. 1992). Note that all aforementioned factors can predominantly introduce de- as well as hyperpolarizations along the axons; the direction of the effect on the activation thresholds depends on the fiber's path relative to the electric field. More precisely,

convex fiber bends relative to the cathode, traversals of a fiber from a medium with high to one with low conductivity (as seen from the cathode), and fiber collaterals away from the cathode increase the excitability, whereas the respective opposite direction would decrease the excitability.

Computer simulations of transcutaneous SCS showed that the abovementioned factors are paramount for the activation of spinal neural structures through surface electrodes (Ladenbauer et al. 2010; Danner et al. 2011). Hot spots of maximal depolarization were identified at the entry point of the posterior rootlets into the spinal cord, at the entry/exit point of the posterior and anterior roots into/from the spinal canal (Fig. 2), and at the branching points of the collaterals from the posterior column fibers. This is somewhat

F

Finite Element Models of Transcutaneous Spinal Cord Stimulation, Fig. 2

Stimulation effect evaluated along sensory structures and motor fibers of the spinal cord and roots. Low-threshold sites are caused by anatomical influences. The straight posterior column (Pcol) fiber shows only slight deviations from zero in its activating function, whereas the fibers in the posterior (PR) and anterior root (AR) are subject to strong de- and hyperpolarization at their entry/exit into/from the spinal cord and canal, respectively. (a) Extracellular potential along selected target fibers generated by transcutaneous stimulation at -1 V. The Pcol fiber is located medially and superficially in the white matter. The abscissa is the distance along the fiber

trajectories from the level of the center of the stimulation electrode. Anatomical relations of the PR and AR fiber are illustrated below the abscissa. (b) Activating functions corresponding to cases in (a). (c) Enlarged view of the box in (a). (d) Top view of the trajectories of the AR and PR fibers and of the simulated Pcol fiber location (x). Arrows indicate the lowest threshold sites. Threshold of the fibers with the paraspinal electrode acting as the cathode, calculated using the model of McIntyre et al. (2002): PR, 16.7 V; AR, 51.7 V; Pcol, 67.4 V (Reproduced from Danner et al. (2011) with permission from Wiley Periodicals, Inc.)

different to epidural SCS, where the points of strongest depolarization are close to the cathode and depend only on anatomically induced hot spots if the leads are located rostral to the fiber's entry point into the spinal cord (Fig. 3). Furthermore, epidural SCS was shown to be more selective (Ladenbauer et al. 2010). For transcutaneous SCS, the computer simulations suggest that with increasing intensity, first fibers in the posterior roots, followed by fibers in the anterior

roots, and eventually fibers in the posterior columns are stimulated.

To summarize, modeling transcutaneous stimulation of the lumbar spinal cord helps to identify the directly activated structures, provides explanations for their selective activation by the distant stimulation, and predicts their recruitment order and points of spike initiation. A more general principle was highlighted. The field produced by a distant electrode in a homogeneous medium would be too non-focal to effectively

Finite Element Models of Transcutaneous Spinal Cord Stimulation, Fig. 3 Stimulation effect (1 V) of transcutaneous and epidural electrodes located over and rostral to the posterior root fibers. The two low-threshold sites (entry into the spinal cord and the canal, respectively) can be seen in case of transcutaneous stimulation. Proximity of the electrode to these hot spots increases the amplitude of the corresponding parts of the activating function.

In case of epidural stimulation, the electrode placed over the fiber introduces strong, local deflections of the potential distribution and the activating function at the level of the contacts of the electrode, whereas the electrode located rostral to the fiber introduces an electric potential and activating function along the fiber similar to those in case of transcutaneous stimulation. Arrows indicate the spike initiation sites

activate neural structures. Rather, the anatomical properties of neurons and their surrounding tissue allow for strong and localized depolarization. Modeling will further contribute to the development of new, improved, and/or tailored stimulation techniques.

Fitzhugh–Nagumo Model

William Erik Sherwood
University of Utah, Salt Lake City, UT, USA

Definition

The FitzHugh–Nagumo (FHN) model is a mathematical model of neuronal excitability developed by Richard FitzHugh as a reduction of the Hodgkin and Huxley’s model of action potential generation in the squid giant axon (FitzHugh 1955). Nagumo et al. subsequently designed, implemented, and analyzed an equivalent electric circuit (Nagumo et al. 1962).

In its basic form, the model consists of two coupled, nonlinear ordinary differential equations, one of which describes the fast evolution of the neuronal membrane voltage, the other representing the slower “recovery” action of sodium channel deinactivation and potassium channel deactivation. Phase plane analysis of the FHN model provides qualitative explanations of several aspects of the excitability exhibited by the Hodgkin–Huxley (HH) model, including all-or-none spiking, excitation block, and the apparent

absence of a firing threshold. A version of the FHN equations which adds a spatial diffusion term models the propagation of an action potential along an axon as a traveling wave. Due to their relative simplicity and ease of geometric analysis, the FHN model and its variants are commonly used in neuroscience, chemistry, physics, and other disciplines as simple models of excitable dynamics, relaxation oscillations, and reaction–diffusion wave propagation.

Detailed Description

Mathematical Model

FitzHugh constructed the FHN equations by slightly modifying the cubic Bonhoeffer–van der Pol model of relaxation oscillations. The original van der Pol equation is a second-order linear differential equation:

$$\ddot{V} + (V^2 - 1)\dot{V} + \phi V = 0, \quad (1)$$

which may be written as two first-order equations by applying the Lienard transformation: $W = -\dot{V} + V - V^3/3$:

$$\dot{V} = V - V^3/3 - W \quad (2a)$$

$$\dot{W} = \phi V. \quad (2b)$$

For all $\phi > 0$, the origin in system Eq. 2 is an unstable fixed point surrounded by a globally stable limit cycle. FitzHugh’s modification to Eq. 2 added linear terms which shifted the fixed point and made it stable (FitzHugh 1955):

$$\dot{V} = V - V^3/3 - W + 1 \quad (3a)$$

$$\dot{W} = \phi(V + a - bW). \quad (3b)$$

Here a , b , and ϕ are positive constants; FitzHugh’s original values were $a = 0.7$, $b = 0.8$, and $\phi = 0.08$.

The variable V is taken to represent the membrane potential of the neuron, the parameter I is the applied current, and W is a “recovery” variable

which represents the combined effects of sodium channel deinactivation and potassium channel deactivation.

There is a separation of timescales between the two variables that is set by the parameter ϕ , normally taken to be much smaller than unity in order to produce relaxation oscillations. That is, the evolution of V , as determined by Eq. 3a, occurs on a timescale of order $O(1)$, and, following Eq. 3b, W evolves on a timescale of order $\phi \ll 1$ (except at transitions; see below). Hence, V and W are referred to as the *fast* and *slow* variables, respectively.

Nagumo’s Circuit Model

Using an electric circuit that included a tunnel diode, Nagumo, Arimoto, and Yoshizawa qualitatively modeled a number of axonal behaviors (Nagumo et al. 1962). The circuit consists of a capacitor (representing membrane capacitance) and a tunnel diode (representing the nonlinear dynamics of the fast membrane current) in parallel with a resistor (representing channel resistance), an inductor, and a battery (these last three components being in series). The dynamics of the tunnel-diode circuit shown in Fig. 1 are described by the equations:

$$CV\dot{V} = I - F(V) - W \quad (4a)$$

Fitzhugh–Nagumo Model, Fig. 1 Nagumo et al.’s electric circuit. (Adapted from Nagumo et al. (1962))

$$L\dot{W} = E - RW + V, \quad (4b)$$

where C is the circuit's capacitance, R is the circuit's resistance, E is the battery's potential, L is the circuit's inductance, and I is an applied current. The variable V represents the voltage drop across the entire circuit, and the variable W represents the current through the resistor–inductor–battery circuit branch.

The $F(V)$ term expresses the current flowing through the tunnel diode as a function of voltage across it. When $F(V)$ is cubic, Eq. 4 may be easily transformed into Eq. 3; if R is eliminated from the circuit, one obtains the van der Pol Eq. 1. Thus FitzHugh's equations and Nagumo's circuit model are equivalent.

Phase Plane Analysis

The (fast) V -nullcline, given by

$$W = V - V^3/3 + I, \quad (5)$$

and the (slow) W -nullcline, given by

$$W = (V + a)/b, \quad (6)$$

are the phase plane structures which organize the FHN system's dynamics. The (left) local minimum and (right) local maximum of the cubic V -nullcline are typically referred to as its “knees.” The knees divide the V -nullcline into three “branches,” left, middle, and right.

The fixed point of the FHN system is located at the intersection of the nullclines. (Under conditions $1 - 2b/3 < a < 1$, $0 < b < 1$, and $b > \phi^2$, there is exactly one fixed point.) The fixed point is stable for low values of applied current I , when it lies on the left branch of the V -nullcline, so that the system remains at rest unless perturbed (quiescence), as shown in Fig. 2a. As I increases, the V -nullcline shifts upward, and the location of the equilibrium shifts toward the middle branch. As the fixed point reaches the left knee of the V -nullcline, it undergoes a Hopf bifurcation, and a limit cycle is born. Thus, for sufficiently large values of I ,

the FHN system simulates tonic spiking, as shown in Fig. 2b.

Near the V -nullcline, $\dot{V}$ is approximately zero, so that motion in the $\dot{W}$ direction predominates, though it is slow because the small parameter ϕ in the $\dot{W}$ equation keeps the magnitude of W very small. Trajectories typically crawl down the left branch and up the right branch of the V -nullcline until they arrive at one of the knees. Once past a knee, the magnitude of $\dot{V}$ rapidly increases, while the magnitude of $\dot{W}$ remains small. The trajectory quickly traverses the region between the left and right branches, so that there is a large change in V in a very short time but very little change in W . Portions of trajectories between branches appear almost horizontal, and they become more nearly horizontal as ϕ decreases. These rapid changes in V as the trajectories switch branches mimic the rapid up- and down-swings of depolarization and hyperpolarization during action potentials, as can be seen in the insets of Fig. 2a, b. The separation of timescales between the V and W variables, as set by ϕ , is necessary for this action potential-like behavior and is the essential characteristic of relaxation oscillations.

When a brief positive current stimulus is applied to the quiescent FHN system, the (unperturbed) fixed point (V^*, W^*) is no longer a fixed point of the perturbed system, and thus the system's state begins to change. (Compare the locations of the fast nullclines and equilibria in Fig. 2a, b.) If its trajectory moves sufficiently far away from the fixed point before the stimulus ends, it will continue to make a large excursion around the right branch of the V -nullcline before returning to the original fixed point, as described above. This behavior models the action potential response of real neurons to depolarizing current pulses. Shifting the initial condition from (V^*, W^*) to $(V^* + V_{stim}, W^*)$ (to the right of the threshold curve near the middle branch of the fast nullcline; see below) produces a largely identical excursive trajectory (see Fig. 2a) and is the most common way to simulate single action potential production in response to external stimulus.

Fitzhugh–Nagumo Model, Fig. 2 Phase planes and sample trajectories for the FHN model Eq. 3 showing quiescence (**a**, left) and tonic spiking (**b**, right). The cubic fast nullcline ($\dot{V} = 0$) is red, the linear slow nullcline ($\dot{W} = 0$) is green, and the equilibrium point (V^*, W^*) is

denoted by a blue dot. Insets show voltage versus time for the sample trajectories in black. The fast nullcline for $I = 0$ is shown as the dotted red cubic curve in **b** for comparison

Geometric Explanation of Spike Generation Phenomena in the Hodgkin–Huxley Model

A number of phenomena which are characteristic of action potential generation in HH-style neuronal models – and, to some extent, in real neurons as well – were first explained by FitzHugh using the FHN model. FitzHugh varied I to simulate stimulation of a neuron by a constant current (setting $I = I_0$ for time $t > 0$) and by rectangular (constant step) currents of various durations (setting $I = I_0$ for time $T_{\text{on}} < t < T_{\text{off}}$) and then studied the FHN model’s response. He discovered that sufficiently large constant current produces spike trains (tonic spiking) via the mechanism described above. He modeled and analyzed other action potential response phenomena with either brief, rectangular, depolarizing (positive) stimuli or with slow current ramps (linearly varying I).

Threshold Phenomena, Small-Amplitude Spikes, and Refractoriness

FitzHugh noted that in the FHN model no single value of V acts as a threshold separating all-or-

none, action potential-like responses to stimulation from quiescent or subthreshold responses. Rather, a curve in the (V, W) plane forms a “quasi-type” threshold, such that for any given value of the recovery variable W_0 , there is a corresponding membrane voltage V_0 which the stimulus must exceed in order to evoke an action potential response (FitzHugh 1955). Trajectories starting to the right of the threshold curve simulate action potentials, while those starting to left of the threshold curve return to the left branch of the fast nullcline without producing a large action potential-like excursion (Fig. 3). Stimuli which fail to shift trajectories past the threshold curve result in small-amplitude trajectories or “bumps” in membrane potential, in both the HH and FHN models. Similar stimulation of biological neurons more typically produces either no response or a very negligible one.

The threshold curve lies near, but not on, the middle branch of the V -nullcline; it is very difficult to trace accurately using standard numerical integration techniques. (The threshold is in fact a canard trajectory which may be computed numerically using continuation methods (Desroches

Fitzhugh–Nagumo Model, Fig. 3 Weak stimuli (current or voltage perturbations) fail to move the system across the quasi-threshold for firing an action potential, resulting in small-amplitude voltage “bumps” (*magenta, blue trajectories*). Sufficiently large stimuli cross the threshold to produce full action potential responses (*black*

trajectory). For intermediate levels of stimulation which leave the system almost exactly at threshold, the system may track the quasi-threshold curve (near the middle branch of the V -nullcline) before turning *left* (no action potential) or *right* (near action potential, cyan trajectory)

et al. 2013)). Because of the difficulty determining whether trajectories would veer to the left or right near the threshold curve, FitzHugh labeled that region of the phase plane “no man’s land.” The HH model has been shown numerically to have a complicated quasi-type spike threshold as well (Guckenheimer and Oliva 2002).

Stimulation by positive current has no discernible effect during the hyperpolarizing downswing of an action potential in both real and HH model neurons. During the repolarization phase, immediately following the downswing, much larger depolarizing input is needed to produce a second action potential than that required for generating the original action potential. These phenomena are termed absolute and relative refractoriness, respectively, and are typically explained in terms of the inactivation of the sodium channels required for depolarization. Phase plane analysis of the FHN model provides a complementary geometric explanation. The FHN model exhibits absolute refractoriness during the period that a trajectory is “jumping” from the right

(depolarized) branch to the left (hyperpolarized) branch of the fast nullcline, and it exhibits relative refractoriness, while the trajectory crawls down the left branch of the fast nullcline toward the equilibrium point (repolarization).

FitzHugh summarized his exploration of the FHN model’s response to brief depolarizing stimulus with a diagram similar to Fig. 4 (FitzHugh 1955, 1961).

Excitation Block

Applying positive external current shifts an HH neuron from quiescence to tonic spiking. In the FHN model, raising I moves the V -nullcline upward and induces repetitive firing as described above. If the magnitude of the stimulus is increased sufficiently, the fixed point will move to the right of the rightmost knee of the V -nullcline and become stable. The periodic orbit corresponding to repetitive spiking will be destroyed in a Hopf bifurcation, and the system will settle into a quiescent state at an elevated resting voltage. Thus, excitation of sufficient

Fitzhugh–Nagumo

Model, Fig. 4 Phase plane map associating FHN system behavior with initial conditions. (Adapted from Fitzhugh 1961)

Fitzhugh–Nagumo Model, Fig. 5 Excitation block: as the applied current I is rapidly increased, the V -nullcline rises and the system passes through a bifurcation whereby the fixed point becomes unstable and a stable periodic orbit is born. So long as the fixed point remains between the two

knees, the system spikes repetitively. Once I is sufficiently high for the fixed point to pass the *right knee*, the stable periodic orbit is destroyed, and the system is attracted to the new, depolarized stable equilibrium. Spiking stops and the membrane voltage remains at an elevated plateau

strength can block the production of spikes (Fig. 5).

Post-inhibitory Rebound Spiking

This phenomenon is also called “anodal break excitation” in older literature. Applying hyperpolarizing current (decreasing I) moves the

V -nullcline downward, maintaining the stability of the fixed point while shifting it down and to the left. When the hyperpolarizing current is turned off, the system is no longer at its fixed point but rather in a state where $\dot{V}$ and $\dot{W}$ are both positive (the “self-excitatory” region in Fig. 4). The system then follows a large excursive

Fitzhugh–Nagumo Model, Fig. 6 Post-inhibitory rebound spiking: injecting negative (hyperpolarizing) applied current I lowers the V -nullcline (red curve) to a new, hyperpolarized level (dotted blue curve) and moves the stable fixed point to a lower voltage level in what would

be the “self-excitatory” region of the phase plane, relative to the unperturbed system with $I = 0$. When the applied current is released, the V -nullcline and fixed point immediately return to their previous positions, and the system travels along a spike trajectory before returning to rest

trajectory around the right branch of the V -nullcline, firing off an action potential in response to the release of inhibition (Fig. 6).

Spike Accommodation

If the applied current I is raised slowly enough in the HH model, the neuron does not fire an action potential. Instead, the neuron remains quiescent, yet excitable, while the resting membrane potential rises. The same phenomenon is seen in the FHN model: as I increases, the V -nullcline shifts upward, and the equilibrium point shifts rightward, losing stability after it passes the left knee. If the shift is slow enough, the trajectory that began at the unperturbed fixed point will remain very close to the moving intersection (now unstable) of the fast and slow nullclines and will present itself as a slow rise in the resting membrane voltage over time (Fig. 7a). During this transition, very tiny perturbations may cause an action potential. Once the intersection of fast and slow nullclines passes the right knee, the fixed point will again be stable, and the system will remain at

an elevating resting membrane potential. The maximum rate of change for I which will produce spike accommodation depends in part on the separation of timescales, as set by ϕ , since it determines the separation between the spike threshold curve and the middle branch of the V -nullcline (Fig. 7b).

Other Forms of the FHN Model

Alternative Formulations

Other formulations of the FHN equations are frequently encountered in the literature. FitzHugh also wrote his model as

$$\dot{x} = c(y + x - x^3/3 + z) \quad (7a)$$

$$\dot{y} = -(x - a + by)/c, \quad (7b)$$

with the constraints that a , b , and c were positive constants satisfying $1 - 2b/3 < a < 1$, $0 < b < 1$, and $b < c^2$ (FitzHugh 1961). This formulation

Fitzhugh–Nagumo Model, Fig. 7 Spike accommodation: increasing the applied current I raises the V -nullcline (red curve, $I = 0$) to a level where the fixed point is unstable (dotted blue curve, $I = 0.5$). When current is

increased very slowly, the membrane voltage tracks the unstable fixed point (a, left). A more rapid current ramp produces a spike as the system is unable to track the unstable fixed point (b, right)

produces a phase plane that is left–right reversed from the figures presented in this article for the FHN system Eq. 3.

Another common reformulation of Eq. 3 is

$$\dot{V} = V(1 - V)(V - \alpha) - w + I \quad (8a)$$

$$\dot{W} = \epsilon(V - \gamma W), \quad (8b)$$

with $\epsilon \ll 1$ and $0 < \alpha < 1$. In this version, the horizontal intercepts of the V -nullcline are conveniently located at 0, α , and 1.

Generalized FitzHugh–Nagumo Systems

Planar dynamical systems which have:

- I. A separation of timescales, i.e., one fast and one slow variable, say, v and w .
- II. A “cubic-like” fast variable nullcline, say, $f(v, w) = 0$.
- III. An approximately linear, monotonic slow variable nullcline, say, $g(v, w) = 0$, which intersects the fast variable nullcline exactly once, may be said to be “generalized FitzHugh–Nagumo systems.” That is, they take the form:

$$\dot{v} = f(v, w) \quad (9a)$$

$$\dot{w} = \epsilon g(v, w) \quad (9b)$$

with $0 < \epsilon \ll 1$. By “cubic-like,” we mean that f is continuous; that there is a single, finite interval of w values for which $f(v, w) = 0$ is satisfied by three v values; and outside that interval $f(v, w) = 0$ generically takes a single v value (Keener and Sneyd 2009) (Fig. 7). Generalized FHN models exhibit dynamics that are equivalent or similar to the canonical FHN model within some range of parameters, but they may have different bifurcation structures. Examples of generalized FHN systems include the piecewise linear models of McKean (approximations of system (Eq. 8a; see Fig. 8a) (McKean 1970; Tonnelier 2003) and Rowat and Selverston (1997) and the Morris–Lecar model (Fig. 8b) (Morris and Lecar 1981)).

Fast–Slow Approximation of Hodgkin–Huxley Dynamics

FitzHugh intended his model to capture the qualitative dynamics of the Hodgkin–Huxley equations during action potential generation. The FHN model approximates the dynamics present in the fast–slow phase plane of the HH equations.

Fitzhugh–Nagumo Model, Fig. 8 Phase planes for the piecewise linear McKendrick model (a, left) and the biophysically realistic Morris–Lecar model (b, right).

Note the cubic-like fast nullclines (red) and the (approximately) linear slow nullclines intersect exactly once; these are generalized FHN systems

The connection between the FHN and HH models can be seen in the following derivation, adapted from Keener and Sneyd (Keener and Sneyd 2009). (FitzHugh gave a similar explanation of the models' connection in FitzHugh (1961)).

The four-dimensional HH model (with variables V , m , n , h) may be reduced to a planar system with one fast variable (V , membrane voltage) and one slow variable (n , potassium activation) as follows. First, sodium activation m is

assumed to equilibrate instantaneously, so that $m = m_\infty(V)$, i.e., the sodium activation timescale is faster than the membrane voltage timescale. Second, the levels of potassium channel activation and sodium channel inactivation are assumed to change on the same timescale and to maintain an approximately constant sum over the course of an action potential, i.e., $h(t) + n(t) \approx 0.8$.

Under these two assumptions, the HH equations reduce to

$$\begin{aligned} \dot{V} &= f(V, n) \\ &= -\left(g, K^{n^4}, (V - E_K), +, gN, a^{m^3}, (V), (0.8, -, n), (V, -, E_{Na}), +, gL, (V, -, V_L)\right)/c \end{aligned} \quad (10a)$$

$$\begin{aligned} \dot{n} &= g(V, n) \\ &= \alpha_n(V)(1 - n) - \beta_n(V)n \end{aligned} \quad (10b)$$

Now (I), there is a wide (though implicit) separation of timescales between the fast and slow variables; (II) $f(V, n) = 0$ is “cubic-like” according to the definition above; and (III) $g(V, n)$ is monotonically increasing, is approximately linear near $f(V, n) = 0$, and intersects $f(V, n) = 0$ exactly once.

Thus, in the fast–slow phase plane, the HH model Eq. 10 is a generalized FHN system, and its behavior and analysis are essentially identical to that of the FHN model (Fig. 9). Note that the “recovery” role played by the slow variable n in the reduced HH Eq. 10 matches the physiological role played by potassium channels in helping to counteract excitation and reset the neuron's membrane potential back to the resting potential.

Fitzhugh–Nagumo

Model, Fig. 9 Phase plane for the fast–slow reduction of the Hodgkin–Huxley equations with parameters set for tonic spiking. Note the *cubic-like shape* of the fast V -nullcline and the *linear shape* of the slow n -nullcline

**FitzHugh–Nagumo Model of Spike Propagation (Traveling Waves)**

With the addition of a diffusion term, the FHN Eq. 3 may be adapted to provide a model of the spatial propagation of an action potential along an axon. Under appropriate boundary conditions to support a traveling wave solution (describing the propagation of the leading edge of the action potential), the equations become

$$V_t = V_{xx} + F(V) - W + I \quad (11a)$$

$$W_t = \phi(V + a - bW) \quad (11b)$$

where

$$F(V) = V^3/3 - V.$$

For traveling wave solutions of the form $V = V(x - ct) = V(\xi)$ and $W = W(x - ct) = W(\xi)$, V and W must satisfy

$$V_\xi = U \quad (12a)$$

$$U_\xi = W - F(V) - cU \quad (12b)$$

$$W_\xi = \frac{\phi}{c}(bW - V - a) \quad (12c)$$

Nagumo et al. first studied the system Eq. 12, taking $F(V)$ to be cubic and $b = 0$ (Nagumo et al. 1962). They found numerical evidence of two traveling wave solutions (homoclinic orbits) when ϕ was sufficiently small. Their numerical results indicated that only the higher-velocity solution was stable and that above a critical value of 0 no traveling wave solutions existed. FitzHugh's later numerical studies reached similar conclusions for $F(V) = V^3/3 - V$ and $b \neq 0$ (FitzHugh 1968). These numerical results have been confirmed analytically (see Scott (1975) for a fuller discussion).

Flicker-Induced Phosphenes

G. Bard Ermentrout¹ and Vincent A. Billock²

¹Department of Mathematics, University of Pittsburgh, Pittsburgh, PA, USA

²National Research Council, US Air Force Research Laboratory, Wright Patterson Air Force Base, OH, USA

Definition

Flicker-induced phosphenes are visual hallucinations – often of simple geometric forms – induced by temporal modulation of spatially unstructured light. Theory suggests that they arise through a combination of resonance and lateral inhibition.

Detailed Description

Experimental Background

Flicker-induced hallucinations are sometimes called phosphenes to distinguish them from the over-sensationalized hallucinations linked to the five melodramatic Ds: drugs, dementia, dreams, delirium, and sensory deprivation. Flicker phosphenes were discovered by Purkinje in 1819 while fanning his fingers between his eyes and a gas

light; Brewster (the inventor of the kaleidoscope) noticed similar forms while racing past a sunlit fence with his eyes closed. Fechner and Helmholtz, who used rotating black-and-white disks as weak flicker sources, reported mainly pastel-colored hexagonal and rhomboidal lattices. In modern studies, many observers of strobe lights and flickering displays also report fan-shape, spiral, and concentric circular patterns. These shapes, together with lattices, are known as Klüver form constants and are also seen in migraine, occipital epilepsy, transcranial electric/magnetic stimulation of visual cortex, Charles Bonnet syndrome, binocular ocular pressure, and during early stages of some drug intoxications (Klüver 1966; Billock and Tsou 2012). Ermentrout and Cowan (1979) posited a revealing neural correlate to Klüver patterns: because of a nonlinear mapping between visual space and visual cortex, fan shapes, spirals, and concentric circles all map to visual cortex as gratings of parallel stripes of neural activation (Fig. 1). Scrolling cortical patterns correspond to rotating or pulsating hallucinations. Perceptual lattices can be formed by superposition of neural stripe patterns. Simpler phosphenes like “doughnuts,” wedges, “bowties,” and single arcs all map to single cortical stripes of varying orientation. Thus, if a pattern formation process on visual cortex can produce stripes of activity on visual cortex, the orientation of the induced stripe (s) predicts the nature of the observed hallucination. Ermentrout and Cowan (1979) showed that a simple excitatory-inhibitory neuronal network can produce cortical stripe patterns, and Bressloff et al. (2001) extended this model to simulate some more complicated illusory textures.

Less temporal modulation is required to induce phosphenes with two eyes than one; when one eye is flickered and the other eye is patched, the two eyes alternate in perceptual dominance. During flickered-eye dominance, geometric patterns are generally seen; during patched-eye dominance, observers report blob-like, boiling-like, and swirling amorphous forms that Smythies (1960) called “dark phase patterns.” Billock and Tsou (2007) reported similar patterns that appeared briefly before fan-shape hallucinations in an apparent motion experiment.

Flicker-Induced Phosphenes,

Fig. 1 Typical patterns seen during flickering light and their transformation to cortical coordinates

Precision of flicker is not critical – even random flicker has been used; however, average flicker frequency does matter: Remole (1973) measured contrast required to induce geometric patterns and found resonance-like tuning functions with maximal sensitivity at about 10–18 Hz. Studies differ on what is seen at any given flicker frequency (for a recent example, see Allefeld et al. 2010); in our experience, lattices are more common at low rates (e.g., 8–12 Hz), and geometric patterns are more common at slightly higher rates. Color is common but unpredictable. If the sluggish photoreceptors are bypassed by driving the optic nerve electrically, hallucinations (crescents, horseshoes, smoke ringlike, etc.) are produced by

rates as high as 210 Hz in light-adapted eyes (Wolff et al. 1968).

Although particular phosphenes appear unpredictably, placing a physical pattern in an adjacent field can bias flicker-induced pattern formation to an orthogonal percept, e.g., physical bull's-eyes induce illusory fan shapes (Billock and Tsou 2007, 2010; Fig. 2). Curiously, there is a visibility hierarchy, with fan shapes easiest to induce, then circles, and then spirals. Together with MacKay's (1978) afterimage experiments, this suggests a perceptual opponency between concentric circles and fan shapes and between clockwise and counterclockwise spirals – an opponency also found for perception of physical

Flicker-Induced Phosphenes, Fig. 2 Patterns inducing their complements

patterns under some conditions. Experiments and evidence adduced from other hallucinatory conditions suggest a natural spatial scale for hallucinatory features of about 1–2 mm on visual cortex (comparable to human orientation column width and hypercolumn spacing) and a natural temporal scale of 10–20 Hz (comparable to the EEG alpha and beta bands). Intriguingly, when flicker is synchronized to the subject's alpha rhythm, illusory pattern formation is significantly faster than for unsynchronized trials (Shevelev et al. 2000).

Theory

The key concept in almost every pattern forming system is *lateral inhibition* in space; that is, local activity at one point in space induces activity to nearby neurons but suppresses those more distantly. It is sometimes called a *Mexican hat* (see Fig. 3a). Flicker phosphenes are induced in a limited band of frequencies so this suggests that there is some type of resonance. Rule et al. built on the Ermentrout and Cowan work by adjusting parameters of that model to have some stronger resonance properties. They considered a population of excitatory and inhibitory neurons arranged in a two-dimensional lattice with spatially decaying connections:

$$\begin{aligned}\tau_e \frac{\partial u(x,y,t)}{\partial t} &= -u(x,y,t) + F(\alpha_{ee} J_e(x,y) * u(x,y,t) \\ &\quad - \alpha_{ei} J_i(x,y) * v(x,y,t) - \theta_e + I_e(t)) \\ \tau_i \frac{\partial v(x,y,t)}{\partial t} &= -v(x,y,t) + F(\alpha_{ie} J_e(x,y) * u(x,y,t) \\ &\quad - \alpha_{ii} J_i(x,y) * v(x,y,t) - \theta_i + I_i(t)).\end{aligned}\quad (1)$$

Here, $J_e(x,y) * u(x,y,t)$ is the two-dimensional spatial convolution of the connection strength, J_e , with the excitatory neural activity, $u(x,y,t)$. (The inhibitory activity is $v(x,y,t)$.) Both J_e and J_i are Gaussians with the spatial decay of J_e shorter than that of J_i so that the net effect is a Mexican hat. $I_e(t)$, $I_i(t)$ are spatially uniform inputs to the excitatory and inhibitory populations. In absence of stimuli, there is a stable homogeneous rest state, $u(x,y,t) = \bar{u}$, $v(x,y,t) = \bar{v}$, and perturbations of this decay to the rest state with a frequency of about 12 Hz (see Fig. 3b).

Keeping in mind Fig. 1, we see that pinwheels and bull's-eye patterns correspond to vertical and horizontal stripes in cortical coordinates. Diagonal patterns in cortical coordinates transform to spiral patterns of perception and lattice, and honeycomb cortical patterns transform to distorted lattices of similar patterns. Thus, to model flicker-induced patterns, we want our cortical network to generate simple geometric patterns like hexagons, rectangles, and stripes of various orientations.

Our network is spatially homogeneous in the sense that homogeneous inputs and initial conditions lead to homogeneous outputs. However, small amounts of noise or heterogeneity will break this symmetry. If the homogeneous system is stable, then the small effects will be dampened and ameliorated. However, if the homogeneous state is unstable, then certain spatial modes will be amplified and patterns will form. Rule et al. (2011) showed that with the parameters as in Fig. 3, patterns emerged at specific frequencies and only in a limited range. By looking at spatially periodic perturbations of the homogeneous state, they were able to compute boundaries in the period and amplitude of the stroboscopic flicker where the homogeneous pattern was

Flicker-Induced Phosphenes, Fig. 3 (a) Mexican hat connectivity pattern and (b) phase-plane showing damped oscillations

unstable. They also simulated equations (see Eq. 1) as the period and amplitude of the stimulus varied. Fig. 4 shows the results of these

simulations. At high frequencies of light (low periods), the patterns are stripes while at low frequencies (periods larger than 100 ms), they

Flicker-Induced Phosphenes,

Fig. 4 Phase diagram of spontaneous flicker-induced patterns as the amplitude and period of the stimulus vary. Contours represent the linear stability theory

are dominated by hexagonal and rectangular patterns. However, note that both classes of patterns are seen in both low and high frequency flicker. This figure also shows the boundaries computed by a stability analysis of the homogeneous state. The boundaries guarantee that within them, the homogeneous state is unstable and outside of them, it is stable. Patterns seen on the outside of the boundaries are numerical inaccuracies; more accurate simulations at the border confirm the stability of the resting state.

In Pearson et al. (2016), the authors further tested the idea that flicker phosphenes arise from a dynamic instability by reducing the stimulus space to effectively one-dimension. The authors flickered only an annulus and subject then reported that there were periodic blobs that rotated in either a clockwise or counterclockwise manner. They suggested the rotation was a consequence of the activation of motion selective neurons by the perceived spatially periodic flickering hallucination.

In sum, flicker phosphenes have been known and enjoyed for centuries. Using classic ideas of pattern formation coupled with resonance in the

temporal domain, these beautiful patterns can be explained with very few assumptions.

Fly Lobula Plate Tangential Cells (LPTCs), Models of

Hermann Cuntz
Ernst Strüngmann Institute (ESI) for Neuroscience in Cooperation with Max Planck Society, Frankfurt am Main, Germany
Institute of Clinical Neuroanatomy, Goethe University, Frankfurt am Main, Germany

Definition

A network of around 60 highly interconnected interneurons, the lobula plate tangential cells (LPTCs), is at the core of optic flow calculations in the fly visual system. Exquisite data is available

for these cells on their anatomy and electrophysiology *in vivo*, including the characterization of responses to visual stimulation. Consequently, it has been possible to derive models that reproduce the morphology and the detailed electrophysiology of the cells within the network and to associate the features of the network to optic flow computations that it performs. The LPTC network therefore is a prime example of a neural circuit where sophisticated computations, connectivity schemes, and anatomy are understood in a unifying manner.

Detailed Description

Circuit Overview of the Lobula Plate

The lobula plate in the fly is a neural center for course control during flight (Borst and Haag 2002). It encodes visual motion information in a retinotopic manner: Neighborhood relationships in the visual field are conserved within the lobula plate neuropil. Dendritic calcium signals in LPTCs in response to visual motion stimulation reveal this retinotopy (Borst and Egelhaaf 1992). Furthermore, the lobula plate divides into four layers that represent local motion in different directions (right, left, upward, and downward). The biophysics that lead to such an organization, i.e., the computation of local motion information, are currently being unraveled (Eichner et al. 2011; Hassenstein and Reichardt 1956; Maisak et al. 2013; Reichardt 1961; Takemura et al. 2013). The topographic two-dimensional arrangement of the lobula plate provides a structured substrate for the calculation of optic flow features. Dendrites of LPTCs cover large areas of the lobula plate to integrate local motion information. The receptive fields of LPTCs are therefore closely related to their dendritic anatomical layout. Sophisticated optic flow responses ultimately result from combining responses of individual LPTCs by means of a precise network of connections.

The network of LPTCs in the fly is accessible to detailed electrophysiological and anatomical analysis (Borst 2012; Borst et al. 2010; Borst and Haag 2002). When opening the back of the

fly's head, the lobula plate lies flat in full view. Extracellular spikes from the so-called H1 cell, one of the most prominent members of the LPTC family, can easily be isolated and recordings can be sustained over the course of many hours in the living fly (de Ruyter van Steveninck and Bialek 1988). This has led to the H1 cell being a model system for neural coding and information theory (Bialek et al. 1991; Borst and Haag 2001; Rieke et al. 1999). Other LPTCs such as the Horizontal System (HS), Vertical System (VS), and Centrifugal Horizontal (CH) cells are accessible to intracellular electrophysiology using sharp electrodes inserted in their large axons (Hausen 1982a, b). Multiple simultaneous intracellular recordings in conjunction with calcium imaging allowed for studying connections between LPTCs directly (e.g., Haag and Borst 2001, 2002, 2004).

These studies led to the description of a large number of specific connections between different LPTCs within the lobula plate (Borst et al. 2010), as well as a number of heterolateral connections linking both sides of the brain (Farrow et al. 2006; Haag and Borst 2001, 2008). Finally, the readout of optic flow information via descending neurons and the flight control circuitry have been studied in great detail (Geiger and Nüssel 1981; Haag et al. 2007, 2010; Wertz et al. 2008, 2012). A unifying network consisting of simplified LPTC model cells has recently been published (Borst and Weber 2011).

Morphological Models of LPTCs

When filled with a cellular dye, individual LPTCs are uniquely identifiable on the basis of their shape alone. They are therefore ideal candidates to study the relationship between structure and function in dendrites. On the other hand, the dendritic branching patterns of any particular identifiable LPTC do not match precisely when compared in different individuals (Hausen 1982a), indicating that any blueprint for an LPTC's dendritic structure, if it exists, is stochastic in nature. A novel kind of morphological model can reproduce LPTC dendritic structures

(Cuntz et al. 2007a, 2008). The model is based on the intuitive idea that the area covered by the dendritic tree, the so-called dendritic field (Hausen 1982a), determines the dendritic tree structure to a large extent (Cuntz 2012). Synthetic dendritic trees are grown to fill the dendritic fields while housekeeping both the total amount of wiring and the conduction times within the dendrites (Cuntz et al. 2007a). The resulting synthetic dendrites (Fig. 1a) yield quantitatively similar inner branching parameter distributions as their real counterparts (Fig. 1b). Since the same branching model is valid for all cell types, this indicates that the growth principles are similar in different LPTC types and their branching statistics are therefore determined by the dendritic field alone (Cuntz et al. 2008). This type of morphological model has since been shown to reproduce the dendritic and axonal shape of many neurons in a variety of species, cell types, or developmental stages (Budd et al. 2010; Cuntz et al. 2010, 2012).

Single-Cell LPTC Compartmental Models

Detailed compartmental models exist for the three main LPTC types: the HS, VS, and CH cells. These single-cell models include passive properties (Borst and Haag 1996), active properties (Haag et al. 1997), and the responses to large-field visual motion stimulation (Haag et al. 1999). These three LPTC types respond to visual stimulation with graded membrane potential deflections, depolarizing when a stimulus is moved in the preferred direction and hyperpolarizing when the stimulus is moved in the anti-preferred direction. The active models therefore do not produce full-blown action potentials but rather small spikelets as well as rebound spikes after strong hyperpolarization due to a specialized sodium-dependent potassium channel (Haag et al. 1997; note a typo in this paper: the sodium reversal potential should be 100 mV instead of 200 mV; see also Neuron model files at www.treestoolbox.org/hermann/). A number of computations were identified by studying HS and VS cells electrophysiologically in combination with corresponding models. First, it was shown

Fly Lobula Plate Tangential Cells (LPTCs), Models of, Fig. 1 Morphological models of HS and VS cells. (a) Example synthetic dendrites (bottom) grown within the dendritic fields of their real counterpart (top). Synthetic dendrites are marked by an “m” preceding HSE (black), HSN (red), VS2 (green), and VS4 (blue). (b) Some typical branching statistics for real dendrites (left) and synthetic dendrites (right). Each cell is represented by one distribution histogram and mean values (filled squares) with error

bars (standard deviation between individual dendrites) are shown. The branching statistics here are (1) path length to root values for all topological points, (2) branch order values, and (3) surface area values assigned to each topological point after Voronoi segmentation. The latter quantifies how homogeneously the topological points are distributed (Modified from Cuntz et al. (2008))

that the small spikelets in HS and VS cells enhance the transmission of high-temporal-frequency signals that would otherwise be filtered out by the time constant of the membrane (Haag and Borst 1996). Second, local irregularities in the motion signal are filtered out by spatial integration in the dendrite (Fig. 2a), a prime example for a functional interpretation of dendritic morphology (Single and Borst 1998). This feature was reproduced in the corresponding passive compartmental model (Fig. 2b), indicating that the passive membrane filtering properties in combination with the morphological structure are sufficient to explain this computationally relevant aspect of dendritic integration.

Dendritic Networks Performing Image Processing Operations

The fact that the motion image is represented in LPTC dendritic activity allows for image processing operations to be applied directly in the dendrites. The CH cell, for example, does not receive visual inputs directly from local motion elements in the lobula plate but indirectly via electrical synapses from the overlapping dendritic

trees of HS cells (Haag and Borst 2002). A corresponding network model (Cuntz et al. 2003) was designed to accommodate active compartmental models of a ventral CH (vCH), an equatorial HS (HSE), and a southern HS (HSS) cell (Borst and Haag 1996; Haag et al. 1997) (Fig. 3a). When the dendrites are connected to each other with spatially distributed electrical synapses at the overlapping sections of their dendritic trees, the model predicts a blurring effect (Fig. 3b) that has previously been reported in experiments measuring dendritic calcium signals (Dürr and Egelhaaf 1999; Haag and Borst 2002). The model is consistent with the experimentally observed current transfer function, the temporal filtering of sharp transients such as spikelets, and the comparably small decrease in CH cell input resistance during full-field visual stimulation. CH cells also possess inhibitory (Meyer et al. 1986) dendritic output synapses (Gauck et al. 1997). The blurred motion image, as represented in the CH cell dendrites, is passed onto Figure Detection (FD) cells (Egelhaaf 1985a, b, c) via these inhibitory dendritic synapses. This puts the unique properties of the CH cell into a functional context. Subtracting the CH cell’s blurred motion image from the FD cell’s own local motion detector input

Fly Lobula Plate Tangential Cells (LPTCs), Models of, Fig. 2 Dendritic integration of visual motion. (a) Calcium responses to wide field visual stimulation using a grating. For four dendritic locations (1–4), the calcium signal exhibits local fluctuations of the brightness pattern similar to those of the drifting periodic grating. These

fluctuations are filtered out by dendritic integration in the calcium signal recorded at the level of the axon (5). (b) This scenario is reproduced in a passive model of a VS cell using simulated local motion detector inputs (1–3: dendritic locations, 4: axonal location) (Modified from Single and Borst (1998))

F

Fly Lobula Plate Tangential Cells (LPTCs), Models of, Fig. 3 Computation in a dendritic network of LPTCs. (a) Realistic compartmental models of a ventral CH (vCH) cell (green), connected to an HSS and an HSE cell (red). (Left Inset) Original fluorescent staining for comparison. (Right Inset) Location of electrical synapses (white) used for these analyses. (b) Membrane potential spread in the HSS model (top left) and vCH model (top right) after local current injection into HSS. In the bottom panels, potential spread is shown similar to top panels but with unconnected cells; current was injected in HSS (bottom left) and vCH

(bottom right). (c) Two cylinders (HS and CH) are connected by five linear conductances surrounding the location of current injection. In HS the signal spreads following an exponential decay while the CH spread is broader (bottom traces). Since the CH signal is smaller than the HS signal, both were normalized to their maximum value. The spread within the CH cell can be approximated as the sum of the currents through each individual conductance (top traces) spreading passively within the CH cell (Modified from Cuntz et al. (2003))

leads to a sharpening of the original image, equivalent to an enhanced motion contrast. This is consistent with selective laser ablation experiments of the CH cell after which the small-field selectivity of FD cells is eliminated (Warzecha et al. 1993).

The spatial low-pass filter in this LPTC dendritic network is based on a general feature of distributed electrical or chemical synapses. The potential in the second cell is filtered by the membrane of both cells in a sequential manner corresponding to a convolution of the signal

with a kernel determined by the filtering properties of both cells (Fig. 3c). Let $f_1(x)$ and $f_2(x)$ describe the spatial impulse response in the first and in the second dendrite, respectively:

$$f_1(x) = e^{-|x|/\lambda} \quad (1)$$

$$f_2(x) = (1 + |x|/\lambda)e^{-|x|/\lambda} \quad (2)$$

where x represents the dendritic location and λ is the length constant of the dendritic cable. These

Fly Lobula Plate Tangential Cells (LPTCs), Models of, Fig. 4 Computation in axonal network between VS cells. (a) Ten VS cells as obtained from 2-photon image stacks and for which detailed compartmental models were reconstructed. Cells were placed manually according to their position in the lobula plate with neighboring dendritic arborizations slightly overlapping. Suggested connectivity scheme from Haag and Borst (2004) with adjacent cells

coupled electrically between their axons and distal cells inhibiting each other (*schematic-filled spots*). (b) Idealized optic flow field for self-rotation. The vertical components scale linearly with the x-axis (*dashed line*). (c) Voltage transfer (normalized amplitudes) from all different VS cells at the location of the synapses in the axon terminal (Modified from Cuntz et al. (2007b))

equations show that the relative spatial attenuation in the second cell is much smaller than in the first one: $f_1(x = \lambda) = 1/e$ and $f_2(x = \lambda) = 2/e$ (see Cuntz et al. 2003 for details). The filtering by the membrane corresponds to a spatial low-pass (blurring), which in the second cell filters out more high frequencies because of the larger space constant. The amount of blurring is determined by the length constant λ of both cells which in turn depends on the dendritic anatomy as well as on the axial and transmembrane resistance (Rall 1959).

Axonal Networks Extracting Optic Flow Features

As illustrated in the preceding example, the precise location of the synapses and the geometrical arrangement of dendrites and axons within the network are crucial for some of the computations that occur in the lobula plate. The network of VS cells (Fig. 4a) is another example for this type of highly selective connectivity. Their dendrites sequentially cover slightly overlapping stripes along the rostrocaudal axis of the lobula plate. However, apart from the expected sensitivity of their responses to vertical motion in large vertical stripes of the visual field, VS cells exhibit more complex receptive fields reaching beyond the

receptive field size expected from the retinotopic location of their dendrites (Krapp et al. 1998; Krapp and Hengstenberg 1996; Laughlin 1999). The complex receptive fields of VS cells roughly match the optic flow that occurs during rotational flight maneuvers of the fly around its own axis (rolling rotation, see Fig. 4b).

How do these properties arise? A number of experiments have indicated that VS cells are connected to each other via their axons in a chain-like manner (Farrow et al. 2005; Haag and Borst 2004, 2005). Moreover, distant VS cells inhibit each other reciprocally. After tuning synaptic conductances and membrane parameters in a network of anatomically realistic VS compartmental models (Fig. 4a), the observed current transfer between VS cells in the network and other experimental measures are reproduced in detail (Cuntz et al. 2007b; Elyada et al. 2009). Interestingly, the VS network thereby effectively implements a triangular filter (Fig. 4c). The linear potential decay is the result of a superposition of the potential decaying exponentially from VS1 to more distal VS cells and the same potential inverted via the inhibition decaying exponentially backward from the distal VS cell to the VS1 cell (Cuntz et al. 2007b; Weber et al. 2008). A triangular filter possesses the interesting characteristic of linearly interpolating the inputs. In this way, the VS network

incorporates prior knowledge about the linear relationship of rotational optic flow vectors with horizontal disparity: Fig. 4b clearly shows this linear relationship in the rotational optic flow field (dashed line). Descending neurons that collect the signals from VS cells have been identified and robustly read out the axis of rotation (Wertz et al. 2009).

Acknowledgments I would like to thank Alexander Borst for the helpful discussions and for reading this manuscript.

Definition

The Fokker-Planck equation (FPE) is a partial differential equation that describes the temporal evolution of the probability distribution of a stochastic variable. It is useful to describe the membrane potential distribution of a neuron receiving stochastic inputs. In this context, it has been used

to determine stationary firing rates as well as neuronal responses to time-dependent stimulations. Beyond its application to single neuron dynamics, the FPE is useful to analyze in a self-consistent way the behavior of an ensemble of interacting spiking neurons and in particular the emergence of neural rhythms.

Historical Remarks

The Fokker-Planck equation is named after Adriaan Fokker and Max Planck who introduced it to describe the time evolution of the velocity probability distribution for a Brownian particle. Marian Smoluchowski used it to analyze the position distribution of Brownian particles when the particle motion is strongly damped. It was also introduced by Andrei Kolmogorov as the equation governing the evolution of the probability distribution of general memoryless stochastic process (Markov process). An important early use of the FPE was Kramers's analysis of the thermal escape rate of a particle over a potential barrier (see Chandrasekhar (1943) for an early classic review).

The stochastic character of neuronal activity has been recognized and quantified for over half a century. Stochastic models of neuronal spiking were developed from the early 1960s (see Tuckwell (1988) for a detailed exposition), but the usefulness of the FPE in this context has been recognized more recently (see Brunel and Hakim (2008) and references therein).

The Fokker-Planck Equation for a Neuron Receiving Noisy Inputs

The temporal evolution of the membrane potential of a neuron can be described with different degrees of complexity and realism. The simplest spiking neuron models use the membrane potential V as their only variable. They usually combine an evolution equation

$$C \frac{dV}{dt} = -F(V) + I(t) \quad (1)$$

where C is the membrane capacitance, $I(t)$ represent the input current, and $F(V)$ represents the intrinsic membrane dynamics, with a spike reset mechanism to account for the repolarization after action potential emission: when V reaches a threshold V_T , an action potential is deemed to be emitted, and the membrane potential is instantaneously reset at $V_R < V_T$. The classical leaky integrate-and-fire (LIF) model uses a linear F representing a passive membrane of conductance g , $F(V) = gV$ (Lapicque 1907; Knight 1972). Nonlinear F s can be used to represent the voltage-gated opening of (sodium) channels as, e.g., $F(V) = gV - g\Delta_T \exp.[(V - V_s)/\Delta_T]$, in the exponential integrate-and-fire (EIF) model where Δ_T quantifies the sharpness of action potential initiation (Fourcaud-Trocmé et al. 2003).

In many situations, $I(t)$ can be split into an average $\mu(t)$ and a fluctuating noise term $\eta(t)$. When the fluctuating term $\eta(t)$ is well approximated by a white noise, Eq. 1 becomes a particular type of stochastic differential equation, called a Langevin equation. The evolution of the probability distribution $P(V, t)$ of V is then described by the Fokker-Planck equation associated to Eq. 1:

$$C \frac{\partial P}{\partial V} = \frac{\partial}{\partial V} [(F(V) - \mu(t))P(V)] + \frac{\Delta(t)}{2} \frac{\partial^2 P}{\partial V^2} \quad (2)$$

where $\Delta(t) > 0$ measures the amplitude of noise fluctuations, $\langle \eta(t)\eta(t') \rangle = \Delta(t)C\delta(t - t')$. The two terms on the right-hand side of Eq. 2 correspond, respectively, to a deterministic drift term induced by the membrane dynamics and the mean input and a diffusion term coming from the fluctuating part of the input. We have supposed that the mean and variance of the noisy inputs are time dependent since that is useful for some applications, as explained below.

Probability is conserved by the FPE, and a probability current $j_P(V, t)$ is associated to Eq. 2:

$$j_P(V, t) = \frac{-F(V) + \mu(t)}{C} P(V) - \frac{\Delta(t)}{2C} \frac{\partial P}{\partial V} \quad (3)$$

The resetting of the action potential imposes boundary conditions at the action potential

threshold V_T and reset V_R . First, it gives an absorbing boundary condition at V_T , $P(V_T) = 0$. Second, the probability is continuous at the reset potential, but its derivative is discontinuous: there is an entering current at reset potential equal to the exiting probability current through the threshold potential. That is,

$$\frac{\partial P}{\partial V}(V_T, t) = \frac{\partial P}{\partial V}(V_R^+, t) - \frac{\partial P}{\partial V}(V_R^-, t) \quad (4)$$

where the subscript $\pm$ denote the limiting values of the function from upper/lower values of its argument.

Finally, the neuron instantaneous firing rate $r(t)$ is given by the instantaneous probability current through threshold potential:

$$r(t) = -\frac{\Lambda(t)}{2C} \frac{\partial P}{\partial V}(V_T, t) \quad (5)$$

Some Applications

The Fokker-Planck formalism has proven useful for the analysis of single neuron and network dynamics in the presence of noise. We mention a few applications of the formalism in the following.

Stationary Firing Rates and F-I Curves

The simplest application of the FPE is the determination of the steady discharge rate of a neuron submitted to stochastic inputs. In a steady situation, the time derivative in Eq. 2 vanishes. A first integration simply gives that the probability current is constant in the two membrane potential intervals, between threshold and reset, $V_R < V < V_T$, and below threshold, $V < V_R$. The current actually vanishes in this second interval (as the probability of finding a very negative membrane potential does). A second integration then allows the determination of the membrane potential probability distribution. Normalization of the total probability fixes the constant probability current between reset and threshold and determines the steady discharge rate r_s :

$$\frac{1}{r_s} = \frac{2C}{\Delta} \int_{V_R}^{V_T} dU \int_{-\infty}^{V_T} dV \exp \left\{ \frac{2}{\Delta} \int_V^U dW [F(W) - \mu] \right\} \quad (6)$$

This calculation in essence dates back to Kramers's computation of the thermal mean escape time of a particle over a potential barrier (Kramers 1940) and is classic in the present context (see Tuckwell (1988) for early references and Burkitt (2006) for a recent survey). The obtained membrane potential distributions for the LIF and EIF neuron models are shown for illustration in Fig. 1.

Responses to Stimulation in the Presence of Noisy Inputs

A major question in neuroscience is how neurons respond to time-dependent inputs. This question is in particular relevant to the understanding of the speed of information processing in sensory systems. It is therefore useful to determine how a neuron responds to a particular input, the signal $s(t)$, in the presence of other “distracting” inputs. Since the neuron response is provided by its output spikes, this leads to analyze how the neuron spike rate is modified by the signal $s(t)$. This can be performed using Eq. 2 when the distracting inputs can be modeled as white noise. For weak signals, the ensuing spike rate modulation $r_1(t)$ is small, and it is linearly related to the signal through a “spike rate response” function R :

$$r_1(t) = \int_{-\infty}^t dt' R(t-t') s(t') \quad (7)$$

The function R can be determined by linearizing the FPE Eq. 2 and solving the resulting linear equation. This is conveniently performed in Fourier space, i.e., by considering periodic signals of different frequencies ω . Responses to both a varying mean $\mu(t)$ and a varying fluctuation amplitude $\sigma(t) \Delta(t)$ have been computed. For instance, for the simplest LIF model subjected to current inputs, one obtains

Fokker-Planck Equation, Fig. 1 Probability distribution of the membrane potential for the LIF model (*left panel*) and the EIF model (*right panel*) and for stationary input mean $\mu(t) = \mu_0$ and variance $\Delta(t) = \Delta_0$. Parameters: $C/g = 20$ ms, $V_T = 20$ mV, $V_R = 10$ mV, $\Delta_T = 2$ mV, $\mu_0/g = 10$ mV (black curves), 15 mV (orange curves), 25 mV (red curves), and $\sqrt{\Delta_0/g} = 5$ mV. Note that in the LIF model, the distribution is confined to $V < V_T$. It reaches zero at

threshold, and the firing rate is proportional to the slope of the distribution at threshold. On the opposite, for the EIF model, the distribution is nonzero for any V and has an exponential tail at large Vs. For inputs that are in the subthreshold range $\mu_0/g < V_T$, the distributions are close to a Gaussian. For larger inputs, the distribution is strongly affected by spiking (see the cusp at $V = V_R$ due to the probability flux proportional to the firing rate)

$$R_1^{(LIF)}(t) = \int \frac{d\omega}{2\pi} \exp(i\omega t) \tilde{R}_1^{LIF}(\omega), \quad (8)$$

where $R_1^{(LIF)}(\omega)$ can be expressed in terms of a combination of hypergeometric functions (see Brunel and Hakim (2008) for a review). A compendium of different response functions for the LIF and EIF models can be found in Richardson (2007), as well as an efficient numerical method to compute such functions.

Self-consistent Analysis of a Network of Neurons

The FPE gives the probability density of neurons submitted to stimuli that are independent representatives of the same stochastic process. However, it can also be used to analyze in an approximate way the dynamics of a set of interacting neurons by neglecting correlations between neurons, the so-called mean field

approximation. This has served for instance to characterize the spontaneous activity of neurons in a network. It has also been used to determine the parameters region where the neural activity of an ensemble of neurons is spontaneously oscillatory and gives rise to neural rhythms (for more details, see the ► “Population Density Model” long entry).

Some Generalizations

Equation 2 is the simplest form of the FPE for one scalar stochastic variable. More general FPEs can be easily written for multidimensional stochastic evolution. In the context of neuronal evolution, these descriptions arise naturally as soon as several variables are used to describe the neuron dynamics, as in the basic Hodgkin-Huxley model. However, multidimensional FPEs are notoriously more difficult to mathematically analyze than the single variable FPE and their use has been much more limited.

One such case is the use of the Fokker-Planck formalism to study the consequence of membrane resonance at a particular frequency. Resonance can arise for instance when a slow conductance opposes membrane potential changes. In this case, the slowness of the second variable allows for a simple analysis by a reduction of the two-variable model to an effective one-variable model (Richardson et al. 2003).

Colored noise provides another case of interest. The filtering effect of synaptic dynamics replaces, for instance, the white noise η in Eq. 1 by a colored noise. In a minimal description, this can be taken to be an Ornstein-Uhlenbeck process with correlation time τ , and it naturally leads to a two-variable Fokker-Planck description. The analysis performed in the small τ limit shows that noise correlation has important consequences on the high-frequency behaviors of spike rate responses (Brunel et al. 2001).

Finally, the neuronal dynamics can be approximated by a diffusion process only under the approximation that the neuron is submitted to small and numerous independent synaptic inputs. While this appears justified in several in vivo situations, it remains to be assessed whether the “shot noise” case of a few sizable inputs proves more appropriate in other cases (Richardson and Swarbrick 2010).

Forward and Inverse Problems of MEG/EEG

Sylvain Baillet
 McConnell Brain Imaging Centre, Montréal
 Neurological Institute, McGill University,
 Montréal, QC, Canada

Definition

The quantitative analysis of scalp MEG and EEG data continues to generate a very diverse body of research based on the characterization of time-resolved brain activity. Some questions however require a more direct assessment of the anatomical substrate of cerebral dynamics. In many cases, modeling the neural generators of scalp MEG/EEG data is the method of choice. From a

methodological standpoint, MEG/EEG source modeling is an “inverse problem”: a ubiquitous concept in many fields, from medical imaging to geophysics (Tarantola 2004). It builds a framework that helps conceptualize and formalize the fact that, in experimental sciences, models are confronted with observations to test a set of hypotheses and/or to estimate some parameters that were originally unknown. Parameters are quantities that can be changed without fundamentally invalidating the theoretical model. Predicting observations from a model with a given set of parameters is called *forward* modeling. The reciprocal situation where observations are used to estimate some unknown model parameters is an *inverse* modeling problem. The neural sources of scalp signals can be defined in terms of their anatomical location and current-flow orientation in space and amplitude variations in time, which represent the primary unknown parameters of MEG/EEG inverse modeling. To enable the latter, it is crucial to capture how these parameters

contribute to scalp data. Hence, MEG/EEG forward modeling consists in predicting the electromagnetic fields and potentials generated by any arbitrary source model, for any possible location, orientation, and amplitude parameter values. In practice, MEG/EEG forward modeling assumes that some additional key parameters are known, hence are not estimated from the data: the geometry of the head, conductivity of the tissues, sensor locations, etc. (Fig. 1). Importantly, it is established that the general inverse problem consisting in characterizing the sources that generate electromagnetic fields outside a volume conductor has an infinite number of solutions. This issue of nonuniqueness is not specific to MEG/EEG: astrophysicists, for instance, face the same issue to determine the distribution of mass inside a planet by measuring its external gravity field. Hence in principle, an infinite number of source models can fit equivalently any set of MEG and EEG observations. Fortunately, this conundrum is addressed with the powerful

Forward and Inverse Problems of MEG/EEG, Fig. 1 Principles of MEG/EEG forward and inverse modeling: (a) some unknown brain activity generates magnetic fields and electrical potentials at the surface of the scalp. This is illustrated by *black* traces of time series representing measurements on a subset of sensors. (b) A naive illustration of forward and inverse models is

shown, with colored arrowheads as ECDs inside a spherical head geometry. The free parameters of each ECD, e.g., location, orientation, and amplitude, are adjusted by inverse modeling. (c) Residuals, i.e., the difference between the original data and the measures predicted by a source model, are minimized by the inverse modeling procedure

mathematics of regularization, which formalizes how additional contextual information can complement a basic theoretical model and guarantee uniqueness and robustness in the determination of its unknown parameters. A considerable amount of research has been produced on practical methods for MEG/EEG forward and inverse modeling. They actually reduce to a handful of classes of approaches, which are now well identified and contribute to making MEG and EEG source imaging a major neuroimaging technique (Salmelin and Baillet 2009).

Detailed Description

MEG and EEG Forward Modeling

Model of Neural Sources

MEG and EEG forward modeling requires two basic models that are bound to work together in a complementary manner: a physical model of neural sources and a model that predicts how these sources generate electromagnetic fields outside the head. The canonical source model of the net primary intracellular currents within a neural assembly is the electrical current dipole. The adequacy of a simple equivalent current dipole (ECD) model as a building block of cortical current distributions was originally motivated by the topography of scalp MEG/EEG data, which typically consists of dipolar patterns of inward/outward magnetic fields and positive/negative electrical potentials. From a historical standpoint, the ECD model derived from extensive previous work in electrocardiography, where dipolar field patterns are also omnipresent (Geselowitz 1964). However, the complexity of the spatio-temporal dynamics of brain activity is more challenging than that of “cardiac traces.” Therefore, more generic alternatives to the ECD model have been proposed either as higher-order multipoles (Jerbi et al. 2004) also derived from cardiographic research or densely distributed source models (Wang et al. 1992). In the latter case, a large number of ECDs are distributed in the entire brain volume or spatially constrained to the cortical surface, thereby forming a dense grid of

elementary sites of activity, the amplitudes/intensities of which are determined from the data. This latter approach is now the prominent technique of choice for MEG and EEG source imaging (Salmelin and Baillet 2009). To understand how these elementary source models generate signals that are measurable using external sensors, further forward modeling of the sensor array and of the electromagnetic properties of head tissues is required.

MEG/EEG Sensor Arrays

Sensor locations can be readily measured with state-of-the-art MEG devices and ancillary EEG equipment. Sensor locations may also be approximated from montage templates; however, this is suboptimal with respect to the accuracy of subsequent source estimation (Schwartz et al. 1996). This is critical with MEG, as the subject is relatively free to position his/her head within a sensor array of fixed size and shape, although movement compensation techniques have been proposed. Further detailed modeling of the sensor geometry, pickup technology, and online noise-attenuation processes is state-of-the-art in the field.

Head Modeling

Quasistatic Assumptions MEG and EEG forward modeling also consists in identifying the influence of the head geometry and of the electromagnetic properties of its tissues on data formation. This last step is popularly coined “head modeling.” For a given model of elementary neural currents and sensor array, the physics of MEG and EEG are ruled by the theory of electrodynamics (Feynman 1964), which reduces in MEG to Maxwell’s equations and to Ohm’s law in EEG, under quasistatic assumptions. These latter consider that the propagation delay of the electromagnetic waves from brain sources to the MEG/EEG sensors is negligible. The reason is the relative proximity of MEG/EEG sensors to the brain with respect to the expected frequency range of neural sources (up to 1 kHz) (Hämäläinen et al. 1993). This is a very important, simplifying assumption, which has immediate consequences on the computational aspects of MEG/EEG head

modeling. Indeed, the equations of electro- and magnetostatics determine that there exist analytical, closed-form solutions to MEG/EEG head modeling when the head geometry is considered spherical. Hence, the simplest and consequently by far most popular model of head geometry in MEG/EEG consists of concentric spherical layers: with one sphere per major category of head tissue (scalp, skull, cerebrospinal fluid, and brain).

Simplified, Spherical Head Geometry The spherical head geometry has further attractive properties for MEG in particular. Quite remarkably indeed, spherical MEG head models are insensitive to the number of shells and their respective conductivity: a current source within a single homogeneous sphere generates the same MEG fields as when located inside a multilayered set of concentric spheres with different conductivities. The reason for this is that conductivity only influences the distribution of secondary volume currents that circulate within the head volume and which are impressed by the original primary neural currents. The analytic formulation of Maxwell's equations in the spherical geometry demonstrates that these secondary currents do not generate any magnetic field outside the volume conductor (Sarvas 1987). Consequently, the conductivity and radius of each spherical layer have no influence on the measured MEG fields, which is not the case in EEG. This is considered a major advantage for MEG.

Geometrical registration to individual MRI anatomical data improves the adjustment of the best-fitting sphere geometry to the participant's head. A spherical head model can be optimally adjusted to the head geometry or restricted to regions of interest, e.g., posterior regions for visual studies. Another remarkable consequence of the spherical symmetry is that radially oriented brain currents produce no magnetic field outside a spherically symmetric volume conductor. For this reason, MEG signals from currents generated at the gyral crests or sulcal depths are attenuated, with respect to those generated by currents flowing perpendicularly to the sulcal walls. The difference in sensitivity to source orientation is another important contrast between MEG and

EEG (Hillebrand and Barnes 2002). Finally, the amplitude of magnetic fields decreases faster than electrical potentials' with the distance from the generators to the sensors. Hence, it has been argued that MEG is less sensitive to mesial and subcortical brain structures than EEG. An increasing body of experimental evidence and modeling efforts has shown however that MEG can detect neural activity from deeper brain regions (Attal and Schwartz 2013).

Realistic Head Geometry Although spherical head models are convenient, they are poor approximations of the human head shape, which impacts the accuracy of MEG/EEG source estimation (Stenroos et al. 2014). The use of more realistic head geometries, which requires solving Maxwell's equations with numerical methods, has also been proposed. Boundary element method (BEM) and finite element method (FEM) are generic numerical approaches to the resolution of continuous equations over discrete space. In MEG/EEG, geometric tessellations of the different envelopes forming the head tissues need to be extracted from the individual MRI volume data to yield a realistic approximation of their geometry. In BEM, the conductivity of tissues is supposed to be homogeneous and isotropic within each envelope. Therefore, each tissue envelope is delimited using surface boundaries defined over a triangulation of each of the segmented envelopes obtained from MRI. FEM assumes that tissue conductivity may be anisotropic (such as the skull bone and the white matter); therefore, the primary geometric building block needs to be an elementary volume, such as a tetrahedron (Marin et al. 1998).

In practice, the FEM's tessellation step remains tedious and complicated. However, efficient implementations of BEM have been derived recently (e.g., Kybic et al. 2005) and are now readily available in several commercial and academic software applications (Baillet et al. 2011).

An important caveat, especially for EEG, is realistic head modeling also depends on the correct estimation of tissue conductivity values, which are difficult to access *in vivo*. Methods of impedance tomography have been proposed with MRI (Tuch et al. 2001) and EEG (Goncalves et al.

2003) but have had limited practical impact so far. Hence, conductivity values from *ex vivo* models are conventionally considered in MEG and EEG head models (Geddes and Baker 1967).

MEG/EEG Source Modeling

Source Localization Versus Source Imaging

The localization approach to MEG/EEG source estimation assumes that brain activity at any time instant is generated by a relatively small number (a handful, at most) of brain regions. An elementary model, such as an ECD accounting for the local distribution of neural currents, is typically used for each source. The resulting elementary sources can then be overlaid to the subject's MRI volume, for visualization and interpretation. Source localization models are therefore compact representation of distributed physiological currents. Although extremely popular in the 1980s and 1990s, this type of approach is now being gradually abandoned in favor of image-based, distributed inverse models, which are better adapted to streamlined analyses of cohorts of subjects.

MEG/EEG source imaging techniques were inspired from the methods and algorithms contributed by research in image restoration and reconstruction in other fields (early digital imaging, geophysics, and other biomedical imaging techniques). Synoptic images of neural current density are obtained using a dense grid of current dipoles distributed as voxel-like current intensity elements over the entire brain volume or limited to the cortical gray matter surface. The imaging procedure is an estimation of the time-resolved amplitude changes of all elementary currents. Hence, in contrast to the localization model, there is no intrinsic sense of distinct, active source regions *per se*. Explicit identification of activity issued from discrete brain regions usually necessitates subsequent analysis, such as empirical or inference-driven amplitude thresholding. In that respect, MEG/EEG source images are essentially similar to the maps obtained in fMRI, with the benefit of time resolution however (Fig. 2).

Beamforming

The first alternatives to source localization were inspired by radar and sonar data analysis, which also concerns array signal processing. MEG and

Forward and Inverse Problems of MEG/EEG, Fig. 2 Inverse modeling: source localization (a) versus imaging (b) approaches. Source localization consists in decomposing the MEG/EEG generators using a handful of equivalent current dipoles (*ECD*). This is illustrated here from experimental data testing the somatotopic organization of primary cortical representations of hand fingers. The parameters of the single *ECD* have been adjusted on the [20, 40] ms time window following electrical stimulus onset at a given hand finger. The *ECD* was found to

localize along the contralateral central sulcus as revealed from the 3D rendering, after registration to the individual anatomy obtained with MRI. In the imaging approach, the source model is spatially distributed using a large number of *ECD*s. Here, a surface model of MEG generators was constrained to the individual brain surface extracted from T1-weighted MR images. Elementary source amplitudes are interpolated onto the cortex, which yields an image-like distribution of the amplitudes of cortical currents

EEG source scanning techniques have therefore emerged: they proceed by systematically sifting through the brain volume to evaluate how a pre-determined elementary source model would fit the data at every voxel while “blocking” contributions from other sources elsewhere in the brain. Hence, these techniques are also known as spatial filters and beamformers (the simile is a virtual beam directed toward a specific brain region) (Spencer et al. 1992; Hillebrand et al. 2005). In theory, beamformers cannot properly detect signal sources that are strictly synchronized; they are also dependent on the prior characterization of second-order noise vs. signal statistics, which may be challenging in practice (Wax and Anu 1996). Nevertheless, beamforming has now become a popular technique for MEG and EEG source imaging.

Distributed Source Imaging

Imaging source models consist of distributions of elementary dipole sources in the brain volume or on the cortex, generally with fixed locations and orientations (Dale and Sereno 1993; Lin et al. 2006). The parameters to estimate through inverse modeling at each time point are therefore the amplitudes of thousands of elementary dipoles given only tens or a few hundreds of data points. Consequently, this image reconstruction inverse problem is dramatically underdetermined and needs to be supplemented by a priori information. The addition of relevant priors can be properly formulated with the mathematics of regularization, reviewed in the context of MEG and EEG (Baillet et al. 2001). The priors on the source image models may take multiple faces, e.g., in order to promote current distributions with spatial and temporal smoothness, or to penalize solutions with current amplitudes that are not physiologically plausible, or to fit with fMRI activation maps, or to prefer source image models made of piecewise homogeneous active regions, etc. Well-chosen priors may also guarantee the uniqueness of the optimal solution to the imaging inverse problem. Overall, weighted minimum-norm image models are the most popular in the field: they are relatively robust to noise and head model approximations, generate centimeter resolution

images, and are fast to compute. Note that the selection of a particular set of image priors is quite subjective. However, methods have emerged to approach model selection in an in-principle manner (Daunizeau et al. 2006).

Appraisal of MEG/EEG Source Models

Modeling implies dealing with uncertainty, and MEG/EEG forward and inverse modeling has uncertainty everywhere: data are complex and contaminated with various nuisances, source models are simplistic, and head models are obtained from approximated geometries and conductivity properties. The determination of error bounds and confidence intervals on the estimated parameter values is an important issue, which has been researched with either parametric methods (Mosher et al. 1993) or nonparametric resampling techniques (Baryshnikov et al. 2004; Darvas et al. 2005).

Statistical inference and hypothesis testing are other important aspects of the appraisal of MEG and EEG source models; they directly address the neuroscience question that has motivated data acquisition and the experimental design (Guilford and Fruchter 1978). In the context of MEG/EEG, the population samples supporting inference are either trials or subjects, for hypothesis testing at the individual and group levels, respectively. Here too, parametric (Kiebel et al. 2005) and nonparametric (Nichols and Holmes 2002; Pantazis et al. 2005) approaches to statistical inference have been proposed, with the important concern of multiple-hypothesis testing (e.g., at thousands of source locations) kept under control (Fig. 3).

Conclusion

The convergence of forward and inverse modeling techniques with statistical inference solutions has brought electromagnetic source imaging to a considerable degree of maturity that is comparable to other neuroimaging techniques (Lopes da Silva 2013). The practical impact of methods for MEG/EEG data analysis has been considerably multiplied by the emergence of major commercial

Forward and Inverse Problems of MEG/EEG, Fig. 3 MEG source imaging of the response to the presentation of a visual target in a rapid serial visual presentation paradigm. The images show a slightly smoothed version of one participant's cortical surface. Colors encode the contrast of MEG source amplitudes between responses

to target versus control faces. Salient visual responses are detected in the target condition by 120 ms and rapidly propagate anteriorly. By 250 ms and thereafter, strong posterior cingulate responses are detected. The latter are the main contributors of the brain response to target presentation

and academic software applications (Baillet et al. 2011).

The complexity in the data obtained with MEG/EEG source analysis is a direct reflection of the intricate brain dynamics that unfold over multiple spatial and temporal scales. For this reason, MEG and EEG imaging has become a truly unique neuroimaging technique for revealing the fundamental large-scale mechanisms that underlie brain functions and dysfunctions.

Definition

A functional network represents the measured associations between activities recorded from separate brain regions. Many diseases may alter, or be caused by, changes in brain functional connectivity.

Detailed Description

An increasingly popular approach in computational neuroscience has been to conceptualize neural networks as mathematical graphs (i.e., collections of nodes and edges) with nodes representing spatially localized brain regions. Such networks typically fall into two categories: structural networks, in which an edge corresponds to a well-defined anatomical feature, such as a synapse or axon bundle, and functional networks, in which an edge corresponds to a statistical association between measured signals recorded at each node. Functional and structural networks are interdependent – functional networks represent dynamically active subsets evolving on an underlying structural network. Experimental and simulated lesions (i.e., node removals) demonstrate that structural connectivity at a removed site is highly predictive of the extent of functional disruption (Sporns 2010).

The inference of a functional network from time-series data requires a number of choices

(see Fig. 1). These include the following: (1) **Choice of a signal that reflects meaningful neural activity at each node.** Many imaging modalities in neuroscience exist, such as the electroencephalogram (EEG), magnetoencephalogram, functional magnetic resonance imaging (fMRI), and positron emission tomography. (2) **Choice of a coupling statistic to assess associations between the collected activities.** These statistics include linear measures of association (such as the cross-correlation or coherence), generalized linear models, and nonlinear measures. (3) **Choice of a threshold in the coupling statistic.** A high threshold leads to fewer connections as well as fewer false detections.

Functional networks are typically understood in terms of their connectivity, which is quantified by graph measures (see Table 1). For instance, a small-world network is defined by the presence of local interconnectivity between nodes together with a few long-distance connections or “shortcuts” through the network (Watts 2004). These properties are captured by (1) a high degree of clustering (i.e., an abundance of local connections) and (2) a small average path length due to the existence of shortcuts. Such a network is of particular interest in neuroscience, where it has been suggested that the mammalian brain – a hierarchy of parallel local circuits – adheres to a small-world architecture (Sporns 2010). Nested within these choices are other subtle issues such as experimental design, signal processing (e.g., smoothing, artifact removal), and identification of epochs of interest.

A recent development is the use of network-theoretic approaches to study complex neuropathologies such as epilepsy, Alzheimer’s disease (AD), schizophrenia, and autism (Sporns 2010). In each case, neurobiological substrates have been hypothesized, but the bridge between microscopic mechanisms and macroscopic dysfunction manifest in brain signals remains unclear. The goal is to illuminate the issue by relating structural and functional networks. These efforts are only just beginning, but network measures appear to be reliable indicators of disease in a handful of cases. For example, it has been shown that small-world network metrics are significantly

Functional Network Observations of Diseased Brain States, Fig. 1 Illustration of the progression from structural network to functional network. This procedure relies on collecting representative signal from each region of interest (*top*) and identifying significant coupling through

a statistical hypothesis test (*bottom left*). The result is a functional network (*bottom right*). Note that different hypothesis tests (due, e.g., to different choices of threshold) lead to different networks

Functional Network Observations of Diseased Brain States, Table 1 A summary of five connectivity measures commonly associated with graph elements. By taking

averages, one can also compute characteristic measures for an entire graph

Measure	Defined on	Definition	Comments
Degree	Nodes	Number of incident edges	Highly predictive of several other measures.
Clustering coefficient	Nodes	Actual connections among directly adjacent nodes / Potential connections	Relatively large in ‘small-world’ network
Path length	Node pairs	Length of shortest path between two nodes; undefined if nodes are not connected	Relatively short in ‘small-world’ network
Betweenness centrality	Nodes	Fraction of times a node appears in the set of shortest paths	Can be defined similarly on edges
Motif frequency	Sup-graphs	Number of times a particular subgraph (motif) appears	Allows the analyst to identify and focus upon specific patterns of interest

different when generated from fMRI and MEG data recorded from patients with AD and that these features correlate with mini-mental status test scores. The AD network has a larger clustering coefficient (implying abnormally high local efficiency) and longer path length (implying

decreased global efficiency) compared to the healthy network (Bianchi et al. 2010). Another potential use of network analysis is to identify the seizure onset zone (SOZ) in patients with partial epilepsy. It has been suggested that during seizure, patterns of functional coupling change

more drastically within the SOZ than outside it (Kolaczyk 2009). Furthermore, a consistent observation across AD, schizophrenia, and autism is functional network differences in frontotemporal areas – especially the posterior cingulate cortex and frontal midline. In most cases, coupling is reduced, consistent with the deficits in working memory, attention, and executive function observed in each disease. The same diminished functional coupling may also be a feature of attention deficit and hyperactivity disorder (ADHD). Additionally, a significant increase in functional coupling in frontotemporal areas has been reported in schizophrenia patients as well as their relatives, suggesting a possible genetic basis. This increase has been interpreted as a deactivation failure of the task-negative (i.e., “daydreaming”) network, perhaps offering a broad link between biology and behavior. Nevertheless, significant work remains to be done.

Conclusions

Brain imaging studies generate increasingly large data sets. Indeed, simultaneous recording paradigms now incorporate multiple spatial scales (e.g., single-cell/LFP/ECOG) and multiple modalities (e.g., EEG/fMRI). Network theory – a rich, graph-based language for describing complex systems – offers a promising avenue for analyzing complicated statistical relationships in these data sets.

Definition

Cortical control of limb prostheses is a specific type of brain-machine interface (BMI) used to provide motor functions similar to those performed by the upper limbs, such as reaching and grasping. BMIs (also called brain-computer interfaces or BCIs) use neural activity to control external devices. Cortical control of limb prostheses is intended to restore motor function to patients with motor disabilities by allowing the activity of intact brain areas to control the movements of a new actuator.

Detailed Description

BMIs use neural activity from the brain to control external devices (see Fig. 1). This diverse tool has many potential applications. One of the most promising is for the recovery of motor function, where neural activity recorded from intact areas of the central nervous system could be used to restore function to patients with motor disabilities. BMIs could be used to restore motor function for patients with complete paralysis (e.g., due to spinal cord injury or amyotrophic lateral sclerosis), provide control for new end-effectors (e.g., for amputees), or facilitate motor rehabilitation for patients with severe damage to the motor system (e.g., due to stroke). Here, we focus on BMI applications for controlling limb prostheses, where the goal is to restore reaching and/or grasping functions naturally performed by the upper limb.

Cortical neuroprostheses show great potential for motor restoration, with many successful demonstrations of animals and human subjects controlling devices ranging from computer cursors to robotic arms with neural activity (Lebedev and Nicolelis 2006; Schwartz et al. 2006; Schalk and Leuthardt 2011; Wolpaw and Wolpaw 2012; Bensmaia and Miller 2014). Each successive demonstration has improved significantly, both in the provided control accuracy and complexity (e.g., number of degrees of freedom (DOFs) controlled). However, many challenges remain before such devices will be clinically viable solutions for

patients (del R Milan and Carmena 2010; Gilja et al. 2011; Lu et al. 2012). These include improving the movement control provided by BMIs, developing ways to include sensory feedback of movement (i.e., tactile and proprioceptive sensation), and improving neural recording technologies to be practical and safe for real-world settings. Research in each of these interrelated areas is ongoing.

There are many potential implementations of limb cortical prostheses. The key system components are: (1) a method to acquire neural signals, (2) an algorithm to translate neural activity into a control signal (often called a “decoder”), (3) a controlled actuator, and (4) mechanisms to provide feedback to the user. These components, together, create a full BMI system, as illustrated in Fig. 1.

By providing the user with feedback, BMIs create a “closed-loop” control system. This allows the user to move the actuator as desired to accomplish movement goals, much as we naturally move our limbs. Early approaches to BMIs aimed to develop BMI systems that could mimic the natural motor system. For instance, much attention has been directed toward creating decoding algorithms capable of predicting limb movements from neural activity for BMI applications (Jackson and Fetz 2011). However, the presence of feedback in closed-loop contributes significantly to BMI performance via biofeedback mechanisms (Wolpaw et al. 2002; Wolpaw 2007; Fetz 2007; Jackson and Fetz 2011; Green and Kalaska 2011). That is, subjects can volitionally control neural activity to achieve desired actuator movements. Similarly, there are many differences between current BMIs and the natural motor system, which may cause differences in evoked neural activity during natural limb motion and BMI control (Orsborn and Carmena 2013; Golub et al. 2016; Orsborn and Pesaran 2017). Thus, more recent approaches to BMI development focus on designing BMI systems that can be readily controlled in closed-loop, rather than explicitly mimicking the natural neural control of limb movements. For instance, mechanisms such as neural plasticity and/or adaptive algorithms that learn user strategies are being heavily explored

Functional Neuroscience: Cortical Control of Limb Prostheses, Fig. 1 Closed-loop BMIs use neural activity to control movement actuators. The presence of sensory feedback to the user creates a closed-loop control system

(Green and Kalaska 2011; Jackson and Fetz 2011; Wolpaw and Wolpaw 2012).

There are a variety of ways to construct a BMI, with variations on the four primary components and the system architecture. Systems have been developed with a wide range of neural signals, decoding algorithms, controlled devices, and forms of user feedback. What's more, there are many different ways to facilitate the control. For instance, neural activity can control movement kinematics directly (e.g., predicting the actuator's position or velocity), or be used to specify a general class of movement (e.g., moving right versus left). The design choices of a BMI system will ultimately influence its performance and path toward clinical translation. Below, we survey the different methodologies used for upper-limb BMIs, discussing key aspects of each BMI system component. Due to the vast variety of approaches in the field, we particularly emphasize methods based on intracortically-recorded neural activity. Methods primarily used in noninvasive BMI systems are discussed briefly with references to additional information.

Recorded Neural Activity

BMIs require a signal from the brain to facilitate actuator control. Obtaining these signals requires several design choices, including: (1) the method used to obtain the signals, (2) the brain regions selected for control, and (3) determining how to analyze the recorded signals. There are a variety of different methods to obtain neural signals, which capture different aspects of neural activity at different spatial and temporal scales. There are also a variety of brain regions that might be useful for BMI applications. Once the type and source of neural signals are chosen, these signals must be interpreted. That is, features thought to be informative about neural states must be extracted from the raw recorded signal. Note that this processing is separate from "decoding" control signals. The steps inherent in obtaining a neural signal from the brain are illustrated in Fig. 2. Below, we briefly survey commonly used recording methods, the features most commonly analyzed from these

Functional Neuroscience: Cortical Control of Limb Prostheses, Fig. 2 The processing required for obtaining neural signals from the brain. For a given recording method, neural signals require (1) selecting brain regions to record from, (2) extracting meaningful features from the signals, and (3) any additional necessary processing on the signals. These signals are then input into the BMI decoder for translation to a control signal

recording methods, and brain regions frequently used for BMI control.

Recording Methods

There are a variety of neural recording methods, each with advantages and disadvantages. Important considerations for BMI applications include: (1) the ability to reliably extract a control signal for movement, (2) spatial resolution, (3) temporal resolution, (4) the invasiveness, and (5) longevity of the signal for long-term prosthesis use.

Obtaining a signal with sufficient information to provide reliable control signals for the actuator is essential for BMI applications. Neural activity from motor-related brain areas, which modulate activity during executed or imagined movements, are commonly used. However, the signals do not explicitly have to be related to natural movement as long as the user can reliably modulate them to control the actuator (see below for discussion of signal source selection). The signals' spatial and temporal resolution are related to their information-content. Recording methods with low spatial resolution limit the number of independent signals that can be recorded from the brain, which in turn shapes the number of control signals that can be obtained to move the actuator. For example, a recording method that yields a single neural feature can only be used to control a prosthesis with one DOF. Similarly, the temporal resolution of a signal limits how frequently

control signals are obtained, shaping the time-scale of the BMI system. The spatial and temporal resolution of the neural recording method may also be related to a subject’s ability to directly control the neural signal. For instance, subjects controlling BMIs operated with low-spatial resolution neural signals like electroencephalography (EEG) often report mental fatigue. There is also a wide range of subject ability in reliably modulating EEG signals (Allison and Neuper 2010). However, the relationship between neural signal properties and user control is still an open question under significant investigation.

The other key considerations for neural signal selection relate to the translating cortical prostheses to clinical applications in humans. The degree of invasiveness – whether surgery is required, and the degree of medical risk associated with the procedures – is a key concern. Moreover, human patients will require neuroprostheses that function throughout their lifetime, making it essential to be able to record viable signals long term (years to decades). Existing invasive methods, such as intracortical implanted electrode arrays, often show signal decay over time in part due to physiological reactions to the implant (Schwartz et al. 2006; Otto et al. 2012).

Table 1 surveys electrical recording methods commonly used for BMI and their invasiveness, longevity, and spatial resolution. Extensive discussion of signal selection for cortical prostheses applications can be found in Andersen et al. (2004), Schwartz et al. (2006), Otto et al. (2012), and Wolpaw and Wolpaw (2012). Discussion of nonelectrophysiological methods and their properties can also be found in Ramsey (2012) and Srinivasan (2012).

Common Signal Types and Feature Extraction

Each recording method produces varied types of neural signals. How these signals are treated and analyzed varies significantly across methods. Here, we briefly discuss the types of signals commonly used for BMI applications. We focus on electrophysiological recording methods, as these are the most commonly used approaches in BMI. However, magnetic signals like magnetoencephalography (MEG) or metabolic neural signals such as functional magnetic resonance imaging (fMRI) or functional near-infrared spectroscopy (fNIRS) may also be useful for BMI applications. These methods and their applications in BMI have been reviewed in Ramsey (2012), Srinivasan (2012), and Sitaram et al. (2012).

Similarly, many BMIs use signal conditioning or “preprocessing” methods to transform neural features into more advantageous signals for decoding. For instance, dimensionality-reduction techniques can be used on neural ensemble data prior to decoding (Krusienski et al. 2012). We focus primarily on feature extraction itself, and refer the reader to Bashashati et al. (2007), and Krusienski et al. (2011, 2012) for thorough discussion and review of preprocessing methods and issues.

Action-Potentials

Action-potentials of neurons are one type of signal recorded from intracortical electrodes. Because action potentials (or spikes) are “all or nothing” events, these signals are binary. Information is conveyed by the times of action potentials, commonly called a spike-train. The most commonly used feature of spike trains is the firing rate. This captures the frequency of spikes. The firing rate of a neuron at a given time can be

Functional Neuroscience: Cortical Control of Limb Prostheses, Table 1 Electrical recording methods and signals, their spatial scale, and invasiveness. Data is summarized from Schwartz et al. (2006) and Nunez (2012). Abbreviations: EEG electroencephalography, ECoG electrocorticography

Method	Signal type	Scale (mm)	Invasiveness
EEG	Scalp potential	>10	Noninvasive
ECoG	Cortical potential	0.1–10	
Intracortical electrode	Local field potential	0.1–1	Invasive
	Action potentials	0.1	

estimated by counting the number of spikes occurring in a small window ΔT . This is commonly referred to as “binning,” and ΔT represents the bin width (Dayan and Abbott 2001; Krusienski et al. 2012). Firing rate, however, ignores additional information that may be contained in the precise timing of a neuron’s action potentials. Methods to extract information about spike timing have also been employed in BMI applications. For example, point-process models attempt to model a neuron’s temporal firing properties (Dayan and Abbott 2001; Brown et al. 2004; Krusienski et al. 2012).

Action potential signals can be recorded from several different sources. An individual intracortical electrode typically records the activity of a small population of nearby neurons. Electrophysiology techniques and spike-sorting algorithms can be used to isolate the spiking of individual neurons from these signals (Miller and Hatsopoulos 2012). Alternately, the activity of several neurons might be combined together into so-called “multi-unit” activity. Both single- and multiunit neural activity has been used in BMI applications.

Field Potentials

Field potential signals represent the electric fields produced by brain activity. They can be measured at several different scales with various recording methods (Nunez 2012). Intracortical electrodes record microscale potentials called local field potentials (LFP). Electrocorticography (ECoG) methods record mesoscale potentials. And EEG can be used to record macroscale fields. One key difference between each of these methods (and scales of field potentials) is the volume of neural activity contributing to the recorded field potential. LFP signals are thought to reflect local synaptic activity near the recording electrode, while EEG signals reflect aggregate activity of large areas of cortex (on the order of 10 mm) (Schwartz et al. 2006; Nunez 2012).

While the underlying source of these signals varies across recording methods, the signal itself is fundamentally the same. It is a continuous-valued, time-varying voltage signal. There are several different types of features commonly

analyzed in field potential signals. Typically, the signals are analyzed in the time or frequency domain (Krusiensi et al. 2012). Temporal features refer to the voltage amplitude over time. Frequency-based features, instead, analyze the spectral information contained within the field potential. Field potential signals commonly show amplitude- and frequency-modulated oscillations that are thought to be informative of neural processes. Thus, the amplitude and/or phase of field potential signals in different frequency ranges can provide useful features for BMI. There are many different methods for estimating spectral components, which are reviewed in Krusienski et al. (2011, 2012). Both temporal and spectral field-potential features must be estimated over time. As with action potential signals, this is typically accomplished by “binning” the signal into small intervals of time. For spectral features, however, this is particularly challenging since the ability to estimate a signal’s spectral components is heavily dependent on the bin sized used (Hayes 1996).

Brain Regions

Another important consideration in BMI applications is what brain region(s) are used for control. Cortical neuroprostheses for reaching and grasping have primarily targeted motor cortical areas. Lower spatial-resolution methods like EEG typically use electrodes centered over motor and sensory areas. Intracortical prostheses commonly implant electrodes in the primary and premotor cortices in areas related to hand and/or arm movement. Many cortical areas are involved with movement, and show a variety of different relationships to movement, which are still under investigation (Riehle and Vaadia 2005; Miller and Hatsopoulos 2012). Pre-motor, supplementary motor, and parietal areas generally show stronger relationships to planned movement goals, rather than executed movements that are represented strongly in primary motor cortices. The types of motor representations and reference frames of movement planning (e.g., planning in visual versus body-centric coordinates) are also thought to differ across areas (Andersen et al. 2010). As such, the neural areas implanted will

influence control. Brain regions may be better suited to different types of BMI architectures or decoders. For example, goal-based signals might be most useful for discrete-movement decoding (Andersen et al. 2010). Intracortical activity from many different motor areas has been used for BMI applications. Additional research is needed to understand if and how BMI control is influenced by brain region. It may also be possible to combine neural activity from multiple brain areas and of different types, though this remains to be carefully investigated.

While the majority of research targets motor areas, BMIs can be controlled with any neural signal. Nonmotor-related BMI systems have been implemented using a variety of brain areas, based on the principles of biofeedback (Fetz 2007).

Controlled Devices (Actuators) and Forms of Control

Neural signals can be used to control a variety of different actuators and with a range of different control schemes. To-date, BMIs have been implemented to control virtual objects like computer cursors, anthropomorphic robots, mobility-based robots, and the user's native limbs via muscle stimulation. Each of these actuators has different potential utility. The properties of the actuator will also influence the complexity of control and the most suitable control algorithms. Movements are described by both kinematic and dynamic properties of the actuator. The movement variables directly controlled by cortical input can be varied. For instance, the neural signal can be used to specify the actuator's position or velocity, or both. Moreover, the coordinate system of control must be considered. Actuators with multiple DOFs, like an anthropomorphic limb-like robot, can be controlled by the end-point or via individual joints (Schwartz et al. 2006). Below, we survey actuators and types of control that have been used in BMI.

Control of virtual objects may be useful for allowing paralyzed individuals to interact with computers. This is of particular interest for

patients with severe paralysis such as tetraplegia (paralysis of all limbs and torso). Virtual cursors also have simplified dynamics compared to real-world actuators that interact with objects within the environment. As such, many preliminary demonstrations of BMI have focused on cursor control. These systems typically use kinematic control implemented in Cartesian space. For example, neural activity is commonly used to control the velocity or position of a cursor moving in two dimensions on a computer screen.

More recent research has focused on cortical control of real-world devices. These systems may have more wide-ranging uses for paralyzed individuals, as they would allow them to interact with the real-world to perform tasks of daily living. Neural activity has been used to control mobility-based robots, like wheelchairs (del R Milan and Carmena 2010). Anthropomorphic robots – robotics with similar appearance and function to human arms – have also been used for BMI (Hochberg et al. 2012; Collinger et al. 2012; Wodlinger et al. 2015). Cortical activity can alternatively be used to drive movements of the user's own body. Functional electrical stimulation (FES) uses electrical stimulation of motor nerves to elicit contractions of muscles, and can be used to evoke movements in paralyzed individuals (Peckham and Knutson 2005). Recent work has investigated using cortical activity to control FES stimulation (Moritz et al. 2008; Ethier et al. 2012). The goal of this approach is to restore natural motor function to paralyzed individuals. This method has been successfully demonstrated in paralyzed animal models.

Robotic and FES-based systems can significantly increase the control complexity of the BMI. First, they typically include many more DOFs than virtual systems. For instance, robots incorporating a shoulder, elbow, wrist, and basic hand grasping include seven DOFs. Incorporating more complex hand movements further expands the number of DOFs. FES systems for upper-limb movement restoration commonly target a minimum of eight muscles (Peckham and Knutson 2005), and more may be necessary for more refined motor control. It is currently unclear if existing BMI approaches will scale as the number

of controlled variables increases. Furthermore, these real-world systems have more complex dynamic properties than cursors which may influence control. For example, biological factors such as muscle fatigue change the relationship between muscle stimulation and evoked movement over time (Peckham and Knutson 2005; Peckham and Kilgore 2013).

There are also many potential control variables in more complex systems. Neural activity can be used to directly set the muscle activations or robot joint movements. Such a scheme allows for the most flexible control, as the user can directly influence all aspects of movement, at the cost of system complexity. Alternative control schemes can be developed to reduce the system complexity. Neural activity could specify kinematic or dynamic parameters of movement in a simplified coordinate system, and algorithms translate these commands into actuations of muscles/joints. For instance, a user could control the end-point position of a robotic limb, and each individual joint position is determined algorithmically. Such methods require assumptions about basic movement properties due to the redundancy in the system (Schwartz et al. 2006; Ting et al. 2012). That is, there are several possible joint configurations that lead to the same end-point position. Hence, these methods constrain the BMI's movement repertoire. Similarly, it may be possible to use "shared-control" where neural activity and automated controls are combined (del R Milan and Carmena 2010). These methods may simplify control of more complex systems, though little work has been done to understand if and how the actuator's properties and control schemes influence closed-loop control.

Decoding Algorithms

Many different decoding algorithms have been used for BMI. The decoding algorithm maps recorded neural activity into a control signal for the actuator. As discussed above, the types of neural and control signals used can be varied. Similarly, the structure of the decoding algorithm is an important design consideration for

developing cortical prostheses. The BMI system architecture – particularly the controlled actuator and neural signal properties – will shape the type of algorithms used.

BMI algorithms can be grouped into several different classes: continuous variable versus discrete movement prediction, generative versus discriminative approaches, and linear versus nonlinear methods. Continuous variable prediction uses neural activity to estimate a continuous-valued movement variable (e.g., end-point velocity), while discrete movement prediction maps neural activity to one of a limited set of movement options (e.g., one of eight target positions). Generative (or inference-based) methods aim to model the relationship between neural activity and movement parameters, which then allows for prediction. Discriminative methods, instead, establish relationships between observed neural activity and movement parameters without learning an underlying model. That is, they perform pattern recognition. Discriminative algorithms, then, are most commonly used for discrete predictions where a limited number of patterns must be learned. Finally, linear decoders use a mapping between neural activity and movement parameters that is linear, while nonlinear decoders use nonlinear mappings.

Below, we overview commonly used classes of algorithms, focusing primarily on continuous-valued prediction methods that are most commonly used in intracortical-BMI applications. The space of algorithms used to predict movement from neural activity is large, and thus we focus primarily on algorithms that have been successfully used in closed-loop BMI applications. Many more algorithms have been explored for open-loop predictions of movement. We also focus on methods for decoding neural signals, independent of their form. Types of signals, features extracted from them, and preprocessing are discussed briefly in section "Recorded Neural Activity." This should not be considered an exhaustive list. Reviews surveying BMI decoding and preprocessing approaches can be found in Schwartz et al. (2001, 2006), Schwartz (2004), Bashashati et al. (2007), Lotte et al. (2007), and McFarland and Krusienski (2012).

Commonly Used Continuous Algorithms

Continuous BMI decoding algorithms translate neural activity into a continuous movement control variable, such as position or velocity.

Direct Mapping

One simple decoding algorithm is to directly use the neural signal, or a linear scaling thereof, for the control signal (see, for instance, Fetz 2007). An example is using the EEG power in two different frequency bands to control the horizontal and vertical velocities of a cursor moving on a screen. Mathematically, these transforms can be described as

$$Y = aX + b$$

where Y and X are the control and neural signals, respectively, and a and b are scaling factors. This basic approach can also use a scaled version of summed neural signals. For instance, the mean firing rate of a small population of neurons can be used as a control signal. While this class of decoders is generative (because it assumes a model for neural activity's relationship to movement), these decoders often do not directly attempt to mimic how neural activity relates to movement in the natural motor system. That is, they are typically not trained using neural and movement data. Instead, parameters are most often specified by the experimenter, imposing a potentially artificial relationship between neural activity and movement.

Population-Vector and Optimal-Linear Estimators

Neurophysiology research in motor cortex revealed that neural activity (particularly single- and multiunit activity in the motor cortices) exhibits cosine tuning to movement parameters such as end-point position and velocity (Miller and Hatsopoulos 2012). That is, a given unit's activity f can be modeled as:

$$f = b_0 + m(\vec{p} \cdot \vec{d})$$

where $\vec{d}$ is movement direction vector, $\vec{p}$ is a cell's preferred direction, b_0 is the baseline

activity, m is the unit's modulation depth. Different neural signals can have different modulation depth, preferred direction, and baseline parameters.

The population-vector algorithm (PVA) and related variants fit cosine tuning models to units, and sum the units' activity weighted by their respective preferred directions to decode movement. Mathematically, the population vector algorithm can be described as:

$$\vec{D} = \sum_{i=1}^N r_i \vec{p}_i = \sum_{i=1}^N \left(\frac{f_i - b_{o,i}}{m_i} \right) \vec{p}_i$$

where $\vec{D}$ is the decoded movement vector, r_i and $\vec{p}_i$ are the normalized-activity and preferred direction of unit i (respectively), and N is the total number of units used for decoding. Normalized activity r_i represents the unit's modulation relative to its baseline activity, scaled by its modulation. The PVA can thus be viewed as giving each unit a "vote" in the resulting movement direction, which is scaled by its modulation. This algorithm has been used to decode a variety of different movement signals, including position, or velocity, and in joint or Cartesian coordinate frames (Dayan and Abbott 2001; Schwartz et al. 2001; Miller and Hatsopoulos 2012; Krusienski et al. 2012).

Training a PVA requires estimating the tuning parameters (b_0 , m , and $\vec{p}$) of each unit. Linear regression techniques can be used to estimate these parameters.

The PVA assumes a uniform distribution of preferred directions, which may not be true for small numbers of units. The optimal linear estimator (OLE) is a variant of the PVA that corrects for nonuniformities in the preferred direction. The OLE decoder has the same form as the PVA, but differs in how the preferred directions are estimated to correct for bias due to nonuniformity. Details can be found in Dayan and Abbott (2001), and Schwartz et al. (2001).

The PVA and OLE are generative decoders. Also note that these algorithms could be used to predict discrete movements (i.e., to one of a set number of targets), rather than continuous movement parameters.

Wiener Filter

The Wiener filter is a linear time-invariant filter (Hayes 1996). BMI applications typically use the discrete filter implementation. The discrete Wiener filter models movement properties $\mathbf{Y}(t)$ as a linear function of past neural activity $\mathbf{X}(t)$:

$$\mathbf{Y}(t) = \mathbf{b} + \sum_{i=-m}^n \mathbf{a}(i)\mathbf{X}(t-i) + \boldsymbol{\epsilon}(t)$$

$$\mathbf{Y} = \mathbf{X}\mathbf{A}$$

where $\mathbf{a}(i)$ are filtering constants at time-lag i , $\mathbf{b}$ is a vector of offsets, and $\boldsymbol{\epsilon}(t)$ is a noise term. The filter uses neural activity across time-lags $[-m, n]$. This can alternately be expressed in matrix form, where $\mathbf{X}$ is a matrix of neural activity where each column is a different unit and rows are time-lagged data and $\mathbf{A}$ is a matrix of the corresponding filter coefficients. Online BMI applications must be causal filters, using only data from the past to predict current/future events. However, open-loop off-line predictions can use noncausal filtering. Wiener filters use the temporal dynamics of neural activity in their predictions, which can be beneficial for increasing decoding power. It also makes these filtering approaches best suited to continuous variable prediction in real-time BMI applications. Wiener filters can be used to predict a variety of different movement variables, including kinematics or dynamics in joint or Cartesian space.

Training a Wiener filter requires setting the filtering constants (matrix $\mathbf{A}$). The coefficients that minimize least-squared error are given by

$$\mathbf{A} = \text{inv}(\mathbf{X}_{\text{train}}^T \mathbf{X}_{\text{train}}) \mathbf{X}_{\text{train}}^T \mathbf{Y}_{\text{train}}$$

where $\mathbf{X}_{\text{train}}$ and $\mathbf{Y}_{\text{train}}$ are vectors of neural and kinematic training data, respectively.

Kalman Filter

The Kalman filter is a linear filter that predicts the state of a system by modeling the state dynamics and their relationship to observed variables (Hayes 1996). In BMI applications, the Kalman filter is used to predict movement variables based on observed neural activity (Schwartz 2004). The

filter models the underlying dynamics of movement (i.e., given a particular end-point position at time t , what is the most likely end-point position at $t + 1$). It also models the relationship between measured neural activity and movement. The final filter estimate is a combination of estimates based on the dynamics model and neural activity measurements.

The KF assumes linear state evolution (1) and state observation models (2):

$$x_t = \mathbf{A}x_{t-1} + w_t$$

$$y_t = \mathbf{C}x_t + q_t$$

where x_t and y_t represent the movement variables and recorded neural activity at time t , respectively. $w_t \sim N(0, \mathbf{W})$ and $q_t \sim N(0, \mathbf{Q})$ are noise terms. The filter is thus specified by the matrices $\mathbf{A}$, $\mathbf{W}$, $\mathbf{C}$, and $\mathbf{Q}$, which are estimated using training data. Based on these models, the Kalman filter recursively estimates the current movement variables x_t based on both the past observed movements ($x_{t-1}, \dots, x_0$) and currently observed neural activity y_t . The recursive estimation scheme is as follows:

1. Estimate of movement variables based solely on state-evolution model (a priori estimate):

$$\hat{x}_{t|t-1} = \mathbf{A}x_{t-1}$$

2. Estimate the covariance (uncertainty) of the a priori estimate:

$$\mathbf{P}_{t|t-1} = \mathbf{A}\mathbf{P}_{t-1}\mathbf{A}^T + \mathbf{W}$$

3. Compute the expected neural activity corresponding to the a priori estimated movement, and the difference between the expected and observed neural activity (measurement residual):

$$\tilde{y}_t = y_t - \mathbf{C}\hat{x}_{t|t-1}$$

4. Compute the covariance (uncertainty) of this measurement residual:

$$\mathbf{S}_t = \mathbf{C}\mathbf{P}_{t|t-1}\mathbf{C}^T + \mathbf{Q}$$

5. Compute an estimate of kinematics incorporating the recorded neural activity (a posteriori estimate):

$$\begin{aligned}\hat{x}_t &= \hat{x}_{t|t-1} + \mathbf{K}\tilde{\mathbf{y}}_t \\ \mathbf{K} &= \mathbf{P}_{t|t-1}\mathbf{C}^T\mathbf{S}_t^{-1}\end{aligned}$$

6. Compute the covariance (uncertainty) of the a posteriori estimate:

$$\mathbf{P}_t = (\mathbf{I} - \mathbf{K}_t\mathbf{C})\mathbf{P}_{t|t-1}$$

Because the Kalman Filter is recursive, it is an infinite-length filter – that is, neural activity at a given time can influence all future predicted movements. By comparison, the length of the Wiener filter (i.e., the number of lags) is a design parameter and is typically set to be finite. The standard Kalman filter only analyzes the neural activity at the current time for prediction. However, n th order extensions to the KF can be used to incorporate time-lagged data as well (Haykin 2002). Because the Kalman filter is designed to incorporate temporal dynamics, it is best suited to continuous decoding.

Training a Kalman filter requires specifying the matrices $\mathbf{A}$, $\mathbf{W}$, $\mathbf{C}$, and $\mathbf{Q}$. These can be estimated using maximum-likelihood estimation methods, which create optimal filters in the least-squares sense. There are also alternative methods to fit filter matrices while constraining the temporal dynamics of the system. For instance, if predicting position and velocity movement variables, it may be desirable to design a Kalman filter that incorporates causal physics (i.e., position is the integral of velocity).

Other Nonlinear Algorithms

Linear algorithms, such as those presented above, are the most prevalent in real-time BMI applications, in part due to their computational simplicity. However, several different nonlinear algorithms have been applied to the problem of predicting movements from neural data. They are briefly summarized here. There are several possible ways to extend the above-described filters to

incorporate data nonlinearity. Nonlinear Kalman filters are a particular example (Haykin 2002). Direct mapping techniques can also use nonlinear functions to map a neural signal into the control signal. There have also been nonlinear Bayesian extensions of the Population Vector Algorithm proposed (Dayan and Abbott 2001; Schwartz 2004).

Similarly, there are many new statistical methods being developed to incorporate Bayesian and maximum likelihood estimation methods to BMI decoding (Dayan and Abbott 2001; Brown et al. 2004; Krusienski et al. 2012). Such models may benefit from incorporating, for instance, models of temporal firing of individual neurons (commonly called point-process models) and/or correlation structures across different neural signals.

Another interesting class of decoding algorithms is artificial neural networks (ANNs). ANNs are interconnected networks of artificial neurons, which can perform linear or nonlinear computations based on their inputs, and with varying connection architectures (Haykin 2009). These networks, thus, can be used to model a variety of data, including highly nonlinear and complex relationships. Feed-forward NNs have directed connections between units such that there are no “cycles” (i.e., starting at a given neuron and moving along its connections, there is no way to return to that neuron). These networks are most common, as they are typically the easiest to train. Recurrent NNs (which include cycles) can demonstrate much more complex and dynamic behaviors, and thus may also be particularly interesting for BMI applications. However, due to their computational complexity, they have only recently been used for closed-loop studies (Sussillo et al. 2012).

Finally, musculoskeletal and neuromechanical models have also been explored for BMI decoding (Kim et al. 2007; Heliot et al. 2010). Musculoskeletal model-based decoders create a biomechanical model of the limb, and use neural activity to drive movements of the model. For instance, neural activity could be used to control the virtual muscles. Neuromechanical models that model properties of the spinal cord (e.g.,

incorporating short-loop reflexes) may also be useful for BMI applications. Incorporating the biomechanical properties of the natural motor system into the decoder may provide beneficial control properties, though closed-loop studies fully exploring these algorithms remain to be done.

Commonly Used Discrete Algorithms

Discrete BMI decoding algorithms translate neural activity into a discrete movement control variable; for instance, decoding a leftward versus rightward movement or a movement to one of a list of candidate locations. Discrete approaches use classification algorithms, which define candidate movement classes (e.g., a list of possible reaching targets) and the neural activity associated with each class. The algorithm then determines the most suitable class based for newly observed neural activity.

There are a wide variety of classification schemes, many of which have been explored in BMI applications. Below, we briefly summarize classification methods in BMI. A thorough algorithm survey and discussion of their strengths and limitations can be found in Lotte et al. (2007), and McFarland and Krusienski (2012).

Linear, discriminative approaches like linear discriminant analysis (LDA) and support vector machines (SVM) are very popular. These methods define hyperplanes that divide data into classes, though they differ in how the hyperplanes are defined. Artificial Neural Networks (ANNs; see section “[Other Nonlinear Algorithms](#)”) can also be used for classification, and many different architectures have been explored in BMI. LDA, SVM, and ANNs are static classification methods, using the neural data from a single time-point for prediction. Dynamic classifiers, instead, use temporal dynamics of neural activity in classification. Hidden Markov models (HMMs) are one class of dynamic classifiers, which determine the likelihood of particular classes based on observed sequences of neural activity.

Each classification method has advantages and disadvantages. One key concern in classification is issues of dimensionality, because the amount of data needed to reliably train a decoder depends strongly on the number of classes being decoded.

Similarly, a decoder varies significantly in their sensitivity to data noise and variance. Recent efforts suggest that combining multiple classification schemes, each with different strengths and weaknesses, may be a particularly beneficial approach in BMI (Lotte et al. 2007).

Decoder Training

There are several possible ways to determine decoder parameters. Decoders are typically trained using supervised methods, where a set of recorded neural data and the corresponding movement variables are known. This training data can be collected as subjects make, observe, or imagine making movements. In clinical applications for individuals with motor disabilities, motor observation or imagery are the only options for collecting training data sets. Natural arm movements, however, may be used in BMI research with able-bodied animal or human subjects.

It is also possible to train many decoders in closed-loop settings. Many groups have developed methods to modify a decoder's parameters as a subject operates a BMI in closed-loop (reviewed in McFarland et al. (2011) and Dangi et al. (2013)). This approach typically uses methods from adaptive filtering. The goal is to dynamically modify the decoder parameters to increase performance over time. This can be achieved by examining a user's neural activity and the movements of the BMI during closed-loop control, and modifying the decoder based on this performance. Supervised approaches use knowledge of what the subject's intentions to correct decoding errors. Unsupervised methods, based on adaptive filtering methods to correct decoding biases, can also be used. Decoder adaptation has several possible uses, including training new decoding algorithms, increasing performance in closed loop, and combating nonstationarity of neural signals over time (Orsborn et al. 2014).

Methods for Providing User Feedback

Closed-loop BMI operation requires that the user have feedback about the actuator movement. This allows the user to perform goal-directed actions with the neuroprostheses. There are several

possible ways to provide this feedback. To date, the majority of BMIs have provided feedback using sensory pathways that are intact even in patients with motor disabilities. For instance, visual feedback of actuator movement can be used to guide movements. Intact pathways can also be used for sensory substitution, where a sensory pathway is used to “display” information different from the usual modality. For example, auditory feedback could be used to convey how much force an actuator is applying, substituting tactile feedback with audition (Schwartz et al. 2006).

Natural and substitutive sensory feedback, however, may have limitations as the complexity of the controlled actuator increases and the amount of feedback required for robust control expands. In natural reach and grasp, proprioceptive and tactile feedback is critical for dexterous movements (Sabes 2011). Incorporating rich somatosensory feedback, then, may be critical for creating viable clinical limb neuroprostheses (Lebedev and Nicolelis 2006; Schwartz et al. 2006; del R Milan and Carmena 2010).

An alternative or additional approach is sensory restoration, aiming to provide sensory information into the central nervous system directly. One promising method for sensory restoration is neural stimulation (Lebedev and Nicolelis 2006; Schwartz et al. 2006; Bensmaia and Miller 2014). Stimulation can be accomplished in a variety of ways. The most popular method for BMI sensory stimulation is intracortical microstimulation (ICMS), where action potentials are evoked from small populations of neurons by injecting small currents into neural tissue using intracortical electrodes. Stimulation of neural tissue has been shown to evoke sensory percepts in animals and humans. Moreover, recent work shows that these artificially-evoked sensory percepts can be combined with other natural sensory stimuli to perform motor- and BMI-control tasks (Venkatraman and Carmena 2011; O’Doherty et al. 2011; Dadarlat et al. 2015). However, these demonstrations are limited to relatively simple forms of feedback. How to convey the rich sensory feedback necessary to represent complex effectors is still unclear. Research into

sensory restoration is ongoing (Bensmaia and Miller 2014).

Gamma Rhythm, Neural Population Models of the

Ingo Bojak
School of Systems Engineering, University of
Reading, Reading, UK

Definition

The classical definition of gamma activity in the electro- and magnetoencephalogram (EEG/MEG) includes all high frequency (>30 Hz) oscillations of brain activity. One can further distinguish the “gamma rhythm” proper, meaning band-limited oscillations of 30–80 Hz with a typical frequency of about 40 Hz, from so-called high gamma

(80–200 Hz) broadband and other, even faster, activity. These high frequency rhythms have been scrutinized extensively, since they become prominent during cognitive tasks. In particular, they often appear to phase lock across distant brain sites, which has led to speculations about their role in integrating distributed neural activity. Neural population models (NPMs) have been used to address the genesis and function of gamma rhythmicity: On one hand, the underlying physiology and the dynamic mechanisms by which gamma activity emerges have been studied in detail. On the other hand, the cognitive aspect has been investigated with functional processing models, mostly for visual feature representation and pattern recognition. As the experimental focus is currently shifting towards high gamma, we can expect that future modeling with NPMs will follow suit.

Detailed Description

Among the classical frequency bands of the EEG/MEG, which also include delta (0–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), and beta (13–30 Hz), “gamma” has been the label assigned to all rapid (>30 Hz) oscillations of electrocortical brain activity (Jasper and Andrews 1938). The amplitude of these oscillations in the EEG/MEG is typically small compared to the lower frequency rhythms. For the sake of

definiteness, often a gamma frequency of around 40 Hz has been discussed in the literature. However, the central frequency of this band-limited brain activity is quite variable in the range of 30–80 Hz, with a bandwidth of about 20 Hz (Muthukumaraswamy et al. 2010; Ray and Maunsell 2011; van Pelt et al. 2012).

A classification of related high frequency phenomena is currently emerging: Firstly, above 600 Hz the dominance of synaptic processes in the electrophysiological signal comes to an end. This “ultrafast activity” (>600 Hz) is related to synchronized bursts (Curio 2005; Hughes 2008) and indexes action potentials (Schroeder et al. 1998, 2001). “Fast activity” (200–600 Hz), like the fast ripples in hippocampus associated with epilepsy (Dzhala and Staley 2004), is likely of similar kind and could be created by multiplexing of synchronous neural firing at lower frequencies (Kohling and Staley 2011). Finally, a so-called “high gamma” band (80–200 Hz) has been identified, which shows very clear power augmentation in task-related brain regions (Brindley and Craggs 1972; Crone et al. 2011), as well as power suppression in the default mode network (Ossandon et al. 2011). It may be an even cleaner signal of cognitive activity than the classical gamma rhythm (Foster et al. 2012). There is, however, currently no agreement in the literature about real or convenient frequency limits between these classes of activities. Furthermore, muscle artifacts with their spectral bandwidth of about 20–300 Hz may compromise noninvasive studies of high frequency neural activity (Muthukumaraswamy 2013). EEG/MEG data hence need to be controlled carefully against potential electromyographic contamination.

A qualitative distinction between the conventional gamma rhythm and the high gamma activity can be made: The latter is not band limited but truly broadband, basically appearing across the entire frequency range without a clear center frequency. We have used 80 Hz above to separate the gamma rhythm from high gamma. However, one might record gamma rhythms with center frequencies of up to 100 Hz and conversely find high gamma broadband changes down to 50 Hz. Furthermore, these brain activities are not mutually

exclusive but can occur simultaneously. It has been suggested that broadband power augmentation actually extends all the way down into the low frequency bands but is in practice masked there by simultaneous narrowband power decreases induced by subcortical regions (Manning et al. 2009; Miller et al. 2007). A different possibility is that the broadband high gamma signal is really just the gamma rhythm observed at higher frequencies. According to this hypothesis spatially more compact neural groups generate higher frequencies (cf. Pfurtscheller and Cooper (1975)), and different such groups would operate at different central frequencies. The recorded signal would sample many such groups as a consequence of volume conduction through tissue, effectively integrating these band-limited processes into one broadband response (Crone and Hao 2002; Crone et al. 2011).

Gamma rhythms became a popular research topic through their apparent association with cognitive function in the cortex (Bressler and Freeman 1980; Galambos et al. 1981; Gray and Singer 1989; Spydell et al. 1979). The appearance of *synchrony* between gamma rhythms in separate parts of the brain has been a particular research focus both for experimental studies (Bressler et al. 1993; Fries et al. 2001, 2008; Gray et al. 1989; Pesaran et al. 2002; Rodriguez et al. 1999; Schoffelen et al. 2005; Tallon-Baudry et al. 1997; Varela et al. 2001) and for theoretical speculations (Engel et al. 1992, 2001; Fries 2005; Singer and Gray 1995; von der Malsburg and Schneider 1986). Additional experimental and theoretical contributions of Freeman and collaborators have been conveniently summarized in a series of papers (Freeman 2003a, b; Freeman et al. 2003; Freeman and Burke 2003; Freeman and Rogers 2003). Furthermore, several comprehensive reviews can be consulted for an overview (Başar 2013; Bastiaansen and Hagoort 2006; Fell and Axmacher 2011; Lee et al. 2003; Tallon-Baudry and Bertrand 1999; Whittington et al. 2000).

Gamma synchrony means that the activity at two different locations in the brain is *phase locked*, with the relative phase between the local gamma waves remaining constant. Initial reports even suggested *zero-lag synchrony*, i.e., in spite of

a physical separation, the relative phase appeared to be zero (Castelo-Branco et al. 1998; Frien et al. 1994; Gross et al. 2004; Rodriguez et al. 1999; Roelfsema et al. 1997). This has led to speculations about the presence of a neural “relay,” for example, thalamus, which could create the appearance of zero lag between two cortical sites (Gollo et al. 2010; Theyel et al. 2010; Vicente et al. 2008; Viriyopase et al. 2012). However, more recent experimental evidence shows non-zero lags (Gregoriou et al. 2009), and a recent review (Uhlhaas et al. 2009) suggests that previous zero-lag results were mostly due to measurements at short distances and experimental difficulties in detecting short lags (Havenith et al. 2009; König et al. 1995; Nikolic 2007; Schneider and Nikolic 2006).

The unique functions speculatively attributed to gamma activity – like binding distributed neural groups into a single task, coding information by using the phase as clock, or gating the communication between distinct neural groups through coherence (Engel et al. 2001; Fries 2005, 2009; Fries et al. 2007; Singer 1999; Uhlhaas et al. 2009; Womelsdorf et al. 2007) – may be an over-interpretation of available data. The variability of the gamma rhythm (Ray and Maunsell 2010), its apparent randomness (Xing et al. 2012), and its disruption through combining stimuli (Lima et al. 2010) could suggest that the gamma rhythm is a reflection of, rather than a means for, cognition. For example, it could reflect the balance of excitation and inhibition at a basic level of processing driven by attention (Brunel and Wang 2003; Niebur et al. 2002; Ray et al. 2013).

While functional interpretations remain rather speculative, the gamma rhythm certainly provides a unique window on brain physiology. Gamma activity is likely driven by, and hence provides experimental access to, networks of inhibitory interneurons (Bartos et al. 2007; Buzsáki and Chrobak 1995; Hasenstaub et al. 2005). There is also a clear correlation between task-related increases in gamma activity and augmentations of the functional magnetic resonance imaging signal (Lachaux et al. 2007; Logothetis et al. 2001; Mukamel et al. 2005; Niessing et al. 2005; Nir et al. 2007), unlike for lower frequency rhythms.

Finally, local field potentials (LFPs), which are the underlying source for the EEG signal, appear to be generated by neural populations at typical scales of around 0.3–0.5 mm when oscillating at gamma frequencies (Berens et al. 2008; Ray and Maunsell 2010). Thus, one can expect gamma activity to be a phenomenon that can be well described with NPMs.

A number of works have addressed gamma activity within the NPM framework. Early results by Zhadin (1984, 1994, 1996) identified a strengthening of gamma activity with cortical excitation and suggested a scaling of frequencies between species with the number of involved cortical cells. König and Schillen provided a comprehensive analysis how visual features can be represented by neural assemblies synchronizing and desynchronizing with gamma oscillations (König and Schillen 1991; König et al. 1992; Schillen and König 1991, 1994). Several other groups also achieved visual processing and pattern recognition using NPM activity compatible with gamma rhythmicity (Campbell and Wang 1996; Grannan et al. 1993; Grossberg and Somers 1991; Hirakura et al. 1996; Horn et al. 1991; Malsburg and Buhmann 1992; Schuster and Wagner 1990; Wang 1995; Yamaguchi and Shimizu 1994). While applications to the visual system are by far the most popular, Baird (1986) has modeled pattern recognition in the olfactory bulb similarly. Finally, Sabatini et al. (2004, 2005) used a continuum approach with an excitatory diffusive term to model visual association fields.

Based on an earlier cortical model (Wright and Liley 1995), Wright and colleagues modeled gamma activity arising from an increase in cortical activation in the presence of inhibitory feedback, as well as zero-lag synchrony supported by long-range excitatory couplings (Chapman et al. 2002; Wright 1997, 1999; Wright et al. 2000). These simulations reproduced qualitatively the results of visual experiments made with moving bars. Cortical synchrony did not require nonlinear gamma activity, but spatially segregated phase patterns could be locked together by triggering it through increasing excitation. Wright (2009, 2011) has consolidated this approach with further parametric studies. In partly overlapping work,

Robinson and collaborators (Robinson et al. 1998, 2001; Wright et al. 2001, 2003) on one hand found that the introduction of reversal potentials led to the appearance of robust gamma resonances (Rennie et al. 2000). On the other hand also improved cortico-cortical activity propagation could lead to spectral enhancements in the gamma range in their model, if the system was marginally stable (Robinson 2005, 2006).

The emergence of spatiotemporal patterns in gamma frequencies, including rotating spiral waves and chaos, was studied by Destexhe (1994). Complex activity arose in spite of an isotropic and homogeneous model structure. Large network size, as well as nonzero conduction delays and sufficiently strong connectivity, was crucial for obtaining these responses. Bojak and Liley (2007) showed that bifurcations from regular alpha oscillations could create localized gamma “hot spots” within about 150 ms, which were furthermore phase-locked with each other; see Fig. 1. It should be noted that their model included reversal potentials (Liley et al. 2002) and that eliciting gamma responses required only relatively minor increases to excitatory thalamic input, compatible with the fact that only 5–10% of all axon terminals in the cortex are thalamic

(Peters 2002). Finally, the model of Steyn-Ross et al. (2009) also needed rapid feedback through reversal potentials to create phase-locking gamma instabilities. They showed that diffusive dynamics due to inhibitory gap junctions increases the spatial extent of such gamma “hot spots.”

It is generally believed that any physiologically accurate model of cognition will have to explain the concurrent appearance of gamma rhythms and related high frequency phenomena in the brain. However, there is a danger in overcommitting to the current state of experimental investigations. Zero-lag synchrony at a distance, once considered to be a crucial feature of gamma rhythmicity, now appears to be mostly an artifact of special circumstances and measurement limitations. Current experimental studies also favor the role of broadband high gamma over the band-limited gamma rhythm for tracking cognitive states. In the face of such changes, it seems prudent for modelers to clarify the physiological mechanisms and relationships of these various high frequency phenomena in the brain first. Nevertheless, the association with cognition makes gamma activity a particularly attractive research field and a testing ground for novel, and potentially far reaching, speculations about the human mind.

Gamma Rhythm, Neural Population Models of the, Fig. 1

Phase-locked “hot spots” emerging on a $(51.2 \text{ cm})^2$ cortical grid (*inset*) after a bifurcation from regular alpha rhythms oscillate with a gamma frequency of approximately 40 Hz (Bojak and Liley 2007). The radial power spectrum (Bojak and Liley 2005) is shown in decibel

Gamma-Aminobutyric Acid Type-A (GABA-A) Receptors, Kinetic Models

Mathew Jones

Department of Neuroscience, University of Wisconsin, Madison, WI, USA

Synonyms

[GABA-A receptor conductance models](#)

Definition

GABA-A receptors are the predominant inhibitory neurotransmitter receptors in the CNS and are protein complexes consisting of an extracellular domain where the neurotransmitter GABA binds to activate a membrane-spanning chloride-selective ion channel. They are often localized in postsynaptic clusters and, upon activation, produce an inhibitory postsynaptic current or potential (IPSC/P). They are the main target for benzodiazepines and general anesthetics, as well as the locus of harmful mutations often associated with epilepsy (Macdonald and Olsen 1994; Cromer et al. 2002). The timecourse of the IPSC is critical in shaping the temporal dynamics of circuit function, including the frequencies of

population rhythms (Whittington et al. 2000). The timecourse of the IPSC, in turn, is shaped by the kinetic properties of the GABA-A receptor complex (Jones and Westbrook 1995).

Most GABA-A receptor conductance models, or kinetic models, are systems of coupled ordinary differential equations that predict the probability of channel state occupancies as a function of time in response to GABA binding and their modulation by drugs or mutations. Such models are important for (a) understanding the regulation of neural function by inhibitory signaling, (b) for understanding the biophysics and pharmacology of GABA-A receptors and related receptors (e.g., nAChRs, GlyRs, 5HT3Rs), and (c) for theoretical advances including accurate computational modeling of neural circuit function and rational drug design.

Detailed Description

Like other kinetic modeling approaches, modeling of GABA-A receptors typically involves enumerating the conformational states available to the protein (e.g., unbound, bound with GABA, open, desensitized, etc.) and assigning transition rate constants between states based on experimental evidence, mostly derived from voltage-clamp measurements of currents in response to application of GABA under varied experimental conditions. The specific conditions that produce the data constrain the type of model that can be developed, each with its own advantages and limitations.

Macroscopic Versus Microscopic Evidence

The most common data available consist of “macroscopic” responses to GABA application (i.e., the ensemble summed current through a large number of receptors), as are produced in two-electrode voltage-clamp experiments in oocytes, or whole-cell recording from HEK293 cells or neurons, or outside-out patch recordings in response to rapid solution exchanges. Such experiments can yield dose–response relations or

reveal the average timecourse of the receptor response, but in general do not directly reveal what states are available or the transition rate constants between states, because the shapes of these responses are determined by the entire combination of states and transitions rather than any single one.

In contrast, one can obtain some “microscopic” information (i.e., direct measurement of state transitions) by observing the statistics of opening and closing of a single ion channel in response to GABA application, for example, in outside-out patch recordings under either steady-state conditions or in response to rapid solution exchange. However, this information is also limited because it is restricted to analysis of transitions between open and closed states. Transitions between two closed states (e.g., unbound to bound or bound to desensitized) are not directly observable in single channel records.

Therefore, neither ensemble measurements nor single channel measurements are sufficient to reveal directly the full underlying microscopic structure of receptor kinetics. The states and transition rates must be inferred by fitting candidate models to the data.

What Does a GABA-A Receptor Kinetic Model Need to Explain?

The most common data available consist of dose–response curves of peak macroscopic current versus GABA concentration that can be fit with a simple two-state model (unbound $\leftrightarrow$ bound) such as that embodied by the Hill equation, where the main free parameters are the affinity constant ($K_d = k_{\text{off}}/k_{\text{on}}$) and a slope factor (n), such that the individual rate constants cannot be uniquely specified. However, lacking rate constants, the resulting model does not allow prediction of the timecourse of current, for example, the shape of the IPSC. The timecourse of macroscopic currents reveals that desensitization occurs, and single channel experiments reveal directly that there are many closed and open states; thus a two-state model is inherently inaccurate. A comprehensive model should be able to account

not only for the macroscopic dose–response curve but also for the number and dwell times of open and closed states observed in single channel recordings, as well as states that cannot be unambiguously quantified in most single channel recordings such as long desensitized states. An accurate model should also provide the forward and backward rate constants for transitions between any pair of states.

These issues are relevant because each state in a model is meant to represent a distinguishable physical conformation of the protein, and the rate constants are logarithmically proportional to the energy barriers between conformations. Furthermore, an accurate model should be able to predict synaptic responses and their alteration by drugs or mutations that alter neuronal computations and behavioral states.

No current model accounts for all of the available data. Existing models tend to be biased toward explaining the specific experiments that produced them. Many features of these models are compatible with each other, but in some cases they produce conceptually different interpretations that either cannot be distinguished from each other based on available evidence or directly conflict with each other.

Cooperativity Models

One class of models is similar to the classical Monod-Wyman-Changeux (MWC) model of cooperative binding, in which the receptor can transition between open, closed, and desensitized states in the absence of modulators such as GABA, benzodiazepines, or anesthetic drugs, but the equilibrium between the different states is altered by the binding of each modulator (Forman 2012). These models are based largely on data from peak dose–response curves (i.e., the maximum current response produced by different GABA concentrations), in the presence and absence of drugs or mutations that modulate receptor function, although in some cases the timecourse of the response is also taken into account (Scheller and Forman 2002). A major advantage of these models is that they naturally lend themselves to treating interactions between the numerous modulatory

sites on GABA-A receptors, via the central underlying concept that all binding sites and gates are energetically coupled to each other such that a transition at any site affects the probability that all other sites will undergo a transition, according to some set of coupling constants. However, a limitation of these models is that transitions are often expressed as equilibrium constants rather than rate constants (but see Scheller and Forman 2002) or that they consider only a small subset of the states that are known to exist.

Stationary Microscopic Kinetic Models

Another class of models focuses on explaining the dwell times and connectivity among states based on the statistics of channel opening and closing observed in single channel records from excised patches collected under true steady-state conditions (Macdonald and Twyman 1992). One advantage of these models is that they make few a priori assumptions about connectivity; for example, they do not insist that all transitions are possible but rather infer connectivity from correlations between observed events. Another advantage is that they account quantitatively for the highly detailed single channel data and can predict certain aspects of macroscopic responses such as dominant features of the IPSC timecourse. A disadvantage is that transitions between closed states, for example, the initial GABA binding step or entry/exit from long desensitized states, are not directly observable in single channel records, and estimation of long closed dwell times in general may be confounded by uncertainty about the number of receptors present in the patch. Thus, the binding rates may depend on the specific model used, and long desensitized states are often omitted for simplicity. Another disadvantage is that extension of such models to account for multiple modulatory interactions becomes unwieldy.

Nonstationary Macroscopic/Microscopic Kinetic Models

A third class of models focuses primarily on explaining the timecourse of the IPSC and other

nonstationary macroscopic phenomena, based on model fitting to the kinetics of responses to transient GABA applications (Jones and Westbrook 1995; Haas and Macdonald 1999; Burkat et al. 2001), often using single channel data as well to directly constrain certain rate constants. In addition to providing predictions of IPSC details, these models also have the advantage of explicitly including desensitized states. In certain circumstances, estimates of binding rates can also be obtained (Jones et al. 1998). Disadvantages are that they are often not sufficiently detailed to account for all of the single channel observations and that their extension to multiple modulatory interactions are also unwieldy.

Pre-activation Step Models

A relatively recent concept in interpreting kinetic data on GABA-A receptors is the idea, first introduced for glycine receptors (Burzomato et al. 2004), that one or more so-called “flip” or pre-activation steps follow GABA binding but precede gating. These models are in some ways a hybrid of previous approaches, in that they incorporate elements of the MWC cooperativity mechanism, but the original versions were derived from stationary microscopic single channel kinetics and later adapted to GABA-A receptors based on peak dose–response curve data (Gielen et al. 2012). A major advantage is that, with minor modifications of coupling constants, they can account for differences in efficacy between full and partial agonists and the effects of certain allosteric modulators. A disadvantage that they share with the first two classes is that long desensitized states are often not included. Also, the estimated dwell times of the “flip” states tend to be too brief to resolve directly.

Gap Junctions in Small Networks

Thomas Nowotny¹ and Paul R. Benjamin²

¹Centre for Computational Neuroscience and Robotics, School of Engineering and Informatics, University of Sussex, Falmer, Brighton, UK

²Sussex Neuroscience, School of Life Sciences, University of Sussex, Brighton, UK

Background/History

Gap junctions are electrical connections between cells that are not primarily gated by chemicals. One of the first accounts of gap junctions was in the crayfish escape system (Furshpan and Potter 1959). Even though the existence of gap junctions

Gap Junctions in Small Networks,

Fig. 1 Examples of small networks where gap junctions play important roles, the crustacean pyloric CPG (a) and the leech heartbeat CPG (b). (a) was created based on Mulloney (1987) and Johnson et al. (2005); (b) was created based on Weaver et al. (2010)

in vertebrates was established in the same year (Bennett et al. 1959), much of the early work on electrotonic coupling has been carried out in small invertebrate circuits. Gap junctions in the mammalian brain were discovered only in the 1970s (see Llinas 1985) and their relevance was appreciated even later.

Typical model systems for the study of gap junctions in small circuits are the crustacean pyloric CPG (Fig. 1a), the *Tritonia* swimming CPG, and the leech heartbeat CPG (Fig. 1b), among others (see Bennett (1977) for review).

Gap junctions are composed of a number of individual electrical channels consisting of two half channels formed of six subunits, provided by each of the connected cells. There are two separate families of proteins that can act as subunits of a gap junction channel: pannexins (originally named innexins when first discovered in insects but later renamed when also discovered in chordates) and connexins, which have thus far only been found in vertebrates. Though having unrelated sequences, proteins of both families have similar 4-trans-membrane domain structure (Panchin 2005; Sáez and Nicholson 2009) for more details. Current flows in the form of ions through the pores of the channels, determined to a first approximation by Ohm's law. Figure 2 illustrates the basic electrical properties of a gap junction.

Gap Junctions in Small Networks, Fig. 2 Typical transmission of membrane potential deflections through a gap junction. The attenuation of the signal and the apparent delay can be understood from the finite input resistance and capacitance of the postsynaptic cell (see inset). The result is an effective low-pass filter (Reprinted (with modifications) by permission from Macmillan Publishers Ltd.: Nat. Neurosci. 3: 7–9, copyright 2000)

The overall conductance of the gap junction is determined by the number of channels in it and the single-channel conductance. The latter has been found to be on the order of 50 pS in neonatal rat heart cells (Burt and Spray 1988), and,

interestingly, individual single channels appear to open and close randomly (Burt and Spray 1988) like other ligand- or voltage-gated channels, i.e., the single channels in a gap junction are not just passive pores in the membrane.

In computational neuroscience, gap junctions are often modeled as simple ohmic conductances between cells. As such they are both inhibitory and excitatory and bidirectional. However, from their first discovery, it has been clear that they are much more complex in reality:

1. Furshpan and Potter's experiments (1959) showed that the gap junctions between the giant axon and giant motor fibers in the crayfish are rectifying, only transmitting currents when the giant axon was depolarized. It is worth keeping in mind that a majority of gap junctions are, however, non-rectifying.
2. Gap junctions are typically low-pass filters, which leads to an appreciable attenuation of the postsynaptic potential elicited by presynaptic spikes (Fig. 2). Interestingly, this phenomenon can render them inhibitory if the effect of the fast, depolarizing part of the presynaptic potential is reduced and a longer and slower after-hyperpolarization is transmitted much more efficiently (see Bennett and Zukin 2004).
3. Gap junctions can be voltage-gated beyond the linear voltage dependence of Ohm's law. Spray et al. (1981) showed that gap junctions between amphibian blastomeres have strong voltage dependence, likely due to the movement of charge within the channel molecules. In contrast to other types of voltage-gated channels, this voltage dependence is mainly determined by the voltage difference between the connected cells rather than the absolute membrane potentials.
4. Gap junctions can be modulated by chemical synapses, for example, in the feeding system of the mollusc *Navanax* (Spira et al. 1980) and the escape motor circuit of teleost fish (Yang et al. 1990). In *Navanax*, for example, gap junction-coupled neurons can essentially be functionally decoupled if separate depolarizing input transiently lowers the input resistance of one of the coupled cells and so largely suppresses any effects of trans-junctional currents.
5. The conductance of gap junctions can depend on extracellular acidity and intracellular Ca^{2+} concentration (Spray and Scemes 1998).
6. It has been shown in vertebrates that the behavior of gap junctions can be altered by phosphorylation of connexins (Musil et al. 1990; Lampe and Lau 2004).

Hypothesized Functions in Small Networks

The most obvious and first to be described function of gap junctions is fast synaptic transmission, for example, in time-critical escape or startle responses (Furshpan and Potter 1959). Another very prominent suggested function is synchronization or coordination of neuronal activity. Egelhaaf and Benjamin (1983) investigated the role of electrotonic coupling between so-called peripheral bursters, intrinsically bursting cells in the nervous system of the snail *Lymnaea stagnalis*. They found that strong coupling between ipsilateral cells led to 1:1 entrainment, such that cells functioned as a single unit. Weaker, contralateral electrotonic connections in contrast led to more rich coordinated activity with changing regimes of 1:1 and 1:2 synchronization.

The formation of single functional unit through strong electrical coupling has been established in the crustacean pyloric CPG, where a pair of pyloric dilator (PD) motoneurons and the anterior burster (AB) neuron form a tightly coupled functional unit (Fig. 1).

A less intuitive function of gap junctions was suggested by Gettings and Willows (1973) in the *Tritonia* pleural ganglia. In this system a group of about 30 trigger group neurons (TGN) are electrically coupled and exhibit accelerating bursting activity. The bursting ends in a synchronous spike in many of the neurons, mediated by the electrical coupling. Burst termination was related to a prolonged after-hyperpolarization of all neurons due to the simultaneous hyperpolarization in many neurons and the ensuing absence of repolarizing currents through the electrical coupling. This is a nice example where the interaction of cellular properties (after spike hyperpolarization) in conjunction with the electrical coupling

generates important and unexpected effects (burst termination in the population of TGN).

Another example of such nontrivial interactions is the combination with chemical synaptic transmission that has been posited to underlie the precise phase relationships in the leech heartbeat CPG (Weaver et al. 2010); see Fig. 1 and the discussion of this work in the next section.

Theoretical Work

A major theme in theoretical and computational work on the role of gap junctions has been synchronization.

Abarbanel et al. (1996) investigated the dynamics of electrically coupled chaotic bursting

neuron models, inspired by the PD neurons in the lobster pyloric CPG (Fig. 1a). They were able to show analytically that the neurons will synchronize perfectly for strong enough coupling while the joint dynamics remained chaotic. For less strong coupling, they identified several distinct regimes of synchronization, including in-phase burst synchronization (but no synchronization of spikes) and, surprisingly, out-of-phase burst synchronization (Fig. 3). Similar effects were also seen in neurons with regular activity (Sherman and Rinzel 1992). Subsequently, Elson et al. (1998) showed that these synchronization regimes can be observed in the lobster pyloric CPG when the electronic coupling between PD neurons is manipulated by the introduction of a simulated additional (or compensatory) electrical coupling

Gap Junctions in Small Networks, Fig. 3 Synchronization phenomena in two electrically coupled chaotic bursting model neurons. Depending on the coupling strength and the properties of the bursting cells, symmetric electrical coupling leads to out-of-phase

synchronization (a), burst synchronization (b), or complete, spike-by-spike synchronization (c) (Reprinted by permission of MIT Press Journals from Abarbanel et al. (1996), © 1996 Massachusetts Institute of Technology)

with dynamic clamp. Similarly, electrically coupled electronic neurons exhibit the same synchronization regimes (Pinto et al. 2000).

Other computational work addressed the role of rectifying gap junctions in regulating the phase relationships of phasic bursting in a model of the leech heartbeat CPG (Fig. 1b). In the medicinal leech, the two tubular hearts operate in two different modes – synchronous contractions in one and a peristaltic rear to front contraction in the other – and the mode of operation swaps between the two hearts regularly. Weaver et al. (2010) showed in a model that only the interaction of inhibitory chemical and electrical connections could reproduce this complex phasing between motoneuron activities on the two sides. Neither inhibitory synapses nor electrical synapses were sufficient on their own. This gives us a glimpse on the potential additional complexity of gap junction function if they interact with other synaptic connections and/or intrinsic cell properties.

Definition

Gap junctions, also known as electrical synapses, provide a means of direct, diffusive neuron-to-neuron communication; this information flow is completely separate from action potential-mediated signaling via chemical synapses. Gap junctions are connexin protein structures that connect the interiors of adjoining cells allowing free flow of transmembrane current. Gap junctions are found in most animal tissues and are widely expressed throughout the mammalian brain, most commonly at the points of contact between dendrites of inhibitory interneurons and between glial astrocytes (Bennett and Zukin 2004). Gap junctions between pairs of excitatory pyramidal cells are rare.

Gap junctions can be modeled as simple Ohmic-resistive connections between neighboring neurons. To date, almost all modeling studies have investigated the bulk effects of resistive coupling among cortical neurons by assembling large networks of discrete spiking neurons, and none of these have considered how resistive coupling might be incorporated into a neural-mass (mean-field) continuum of excitable tissue. The single exception is the mean-field gap-junction model of Steyn-Ross et al. (2007, 2008, 2009, 2010, 2011, 2012, 2013). The continuum population approach allows predictions regarding neural activity and state changes that should be discernible at the scale of EEG electrodes.

Detailed Description

Network Effects of Neuron-to-Neuron Diffusion

Most modeling studies have incorporated gap junctions as resistive connections between pairs of neurons that have been assembled into a neural network of several hundreds or perhaps thousands of individual Hodgkin-Huxley (or similar) spiking neurons. We refer to such networks as “neuron-by-neuron” models to distinguish them from the “mean-field” or population-based approach that describes a spatially averaged continuum of excitable tissue (see next section).

If two adjoining neurons, labeled j and k , are coupled by a resistive gap-junction channel, a current proportional to the voltage difference between those neurons will flow through the gap junction, $I_{\text{gap}} \propto (V_k - V_j)$. This gap current will sum with any ionic flows resulting from action potentials arriving at chemical synapses, I_{syn} , giving a total current entering the capacitive membrane of neuron i as

$$C \frac{dV_j}{dt} = I_{\text{syn}} + I_{\text{gap}} \quad \text{with} \quad I_{\text{gap}} = g \cdot (V_k - V_j) \quad (1)$$

where C is the membrane capacitance and g is the conductance of the gap-junction channel.

It is clear from Eq. 1 that the gap current between coupled neurons can only disappear if the gap-channel conductance g is zero (i.e., the channels are completely blocked) or when the voltage difference $(V_k - V_j)$ between cells is zero, implying that the neuron pair is completely synchronized with identical membrane voltages. Thus, the presence of gap currents will tend to align neuron behaviors, not only during sub-threshold fluctuations but also during periods of active firing. Synchronized behavior has been observed in whole-cell recordings of gap-junction-connected GABAergic (inhibitory) neurons in the cortex (Galarreta and Hestrin 1999; Tamás et al. 2000; Beierlein et al. 2000) and confirmed theoretically in many numerical simulations of conductance-based neuron-by-neuron

networks of interneurons (Traub 1995; Traub et al. 2000; Skinner et al. 1999; Kopell and Ermentrout 2004).

In summary, these modeling works indicate that – although interneuronal gap junctions tend to synchronize neuronal oscillations – they do not instigate global oscillations. This is consistent with mean-field investigations showing that interneuronal gap junctions can modulate GABAergic-generated rhythms to produce phase-coherent activity across the cortical field (Steyn-Ross et al. 2010, 2012).

Although most neural gap junctions form between the dendrites of interneurons, there have been reports of axo-axonal junctions between principal neurons in the hippocampus (Schmitz et al. 2001; Nagy 2012). Network modeling by Traub et al. (2001, 2002) suggests that such connections can generate the fast ripple oscillations seen prior to and during epileptic seizure events and may have a role in epileptogenesis.

Modeling Gap-Junction Diffusion in a Neural Population

Rather than tracking the detailed behavior of individual neurons within a network, continuum models of the cortex describe the spatially averaged activity of large populations of neurons. The neural equations are then expressed in terms of a notional population-averaged neuron represented as an RC integrator of membrane resistance R_m and capacitance C_m , charged by a battery of voltage V^{rest} , the cell's resting potential (see Fig. 1). The neuron's membrane voltage V_m is perturbed by input currents entering from chemical synaptic sources (arising from action potential events) and from gap-junction channels.

From Kirchhoff's law, the total input current I_{in} from chemical and diffusive sources equals the sum of the resistive and displacement currents owing to “ground” (i.e., the extracellular space):

$$\begin{aligned} I_{\text{syn}} + I_{\text{gap}} &= I_{\text{in}} \\ &= (V_m - V^{\text{rest}})/R_m + C_m \frac{dV_m}{dt} \quad (2) \end{aligned}$$

Each neuron receives diffusive inputs from its gap-junction-coupled neighbors. If this per-neuron region of diffusive sensitivity has area a , then using simple Ohm's law arguments, Steyn-Ross et al. (2007) showed that the gap current is given by

$$I_{\text{gap}} = \frac{a}{R} \left[\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right] V_m \equiv \frac{a}{R} \nabla^2 V_m \quad (3)$$

where effective coupling resistance R (shown in Fig. 1) is a fraction of the single-channel gap-junction resistance R_{gap} :

$$R = \frac{R_{\text{gap}}}{N/4}$$

Here, N is the average number of gap junctions per neuron; this is reduced by a factor of 4 on the assumption that these gap junctions are uniformly distributed across each of the four rectangular-grid directions. After substituting Eq. 3, and defining membrane time constant $\tau = R_m C_m$, Eq. 2 can be rearranged to read as

$$\tau \frac{\partial V_m}{\partial t} = (V^{\text{rest}} - V_m) + I_{\text{syn}} R_m + D \nabla^2 V_m \quad (4)$$

Gap Junctions, Neural Population Models and, Fig. 1 Cortical sheet modeled as a 2-D rectangular network of diffusively coupled neurons. The neuron at origin O receives diffusive currents $I_{\text{gap}} = (I_1 + I_2 + I_3 + I_4)$ from four neighboring diffusion cells via coupling resistances R determined by the density and spatial distribution of gap-junction channels (chemical synaptic currents not shown). (Figure modified from Steyn-Ross et al. 2007)

where $D = \frac{aN}{4} (R_m/R_{\text{gap}})$ is the diffusive coupling strength, carrying dimensions of area, so that the ratio D/τ is a diffusion coefficient for voltage change: in time t , a voltage perturbation will diffuse through rms distance $\sqrt{4Dt/\tau}$ on a two-dimensional cortical sheet.

In application, Eq. 4 would be written as a pair of partial differential equations representing the neuron-average soma voltages [i.e., $V_m \rightarrow (V_e, V_i)$] for the excitatory and inhibitory populations, respectively, with distinct diffusion strengths [$D \rightarrow (D_{ee}, D_{ii})$]. In addition, each population receives chemical synaptic current I_{syn} via an incoming flux of both excitatory and inhibitory spike events: $I_{\text{syn}} \rightarrow (I_{ee} + I_{ie} + I_{ei} + I_{ii})$, where, e.g., I_{ie} signifies inhibitory synaptic current entering the excitatory population. Each of these currents is computed as a convolution of the spike rate with a response function (usually biexponential) representing postsynaptic ion-channel kinetics (Destexhe et al. 1989; Steyn-Ross et al. 2009), modulated by the relevant ionic reversal potential (Liley et al. 1999; Rennie et al. 2000).

Estimation of Gap-Junction Coupling Strength

For layers 2 and 3 of cat visual cortex, Fukuda et al. (2006) counted ~ 400 large (L-type) inhibitory interneurons per mm^2 with each neuron making 60 ± 12 (mean $\pm$ SD) gap junctions with neurons of the same type. They reported that serially interconnected neurons could be traced through multiple gap junctions to form a dense, homogeneous syncytium that extended over many columns of the visual cortex. Using the Fukuda data, Steyn-Ross et al. (2007) estimated an upper bound for inhibitory-to-inhibitory ($i-i$) diffusion coupling strength of $D_{ii} \lesssim 0.6 \text{ cm}^2$, but acknowledge considerable uncertainty in this value given that:

- Detection of gap junctions is technically challenging; estimates for gap-junction abundance in cerebral cortex have been increasing over time as laboratory techniques become more sensitive and discriminating.

- Fukuda et al. (2006) only counted connexin-36 (Cx36) junctions; however, there are many other connexin and pannexin types (e.g., Cx32, Cx43) connecting pairs of neurons, pairs of glial cells, and neuron-glial pairs (Nadarajah et al. 1996).
- The value for a , the lattice area of diffusive reception, is sensitive to the shape of the assumed connectivity kernel (e.g., Gaussian vs. top hat).
- The assumed values for membrane resistance $R_m \approx 7.1 \text{ G}\Omega$ and channel resistance $R_{\text{gap}} \approx 290 \text{ M}\Omega$ are average values; these are likely to change dynamically with neuronal activity (Koch 1999; Palacios-Prado et al. 2013).

Unlike the case for inhibitory neurons, there are very few reports for gap-junction connectivity between *excitatory* neurons (Schmitz et al. 2001) and none suggesting the existence of a dense network of e-to-e resistive connections. This implies that, relative to $i-i$ coupling, $e-e$ diffusive coupling strength is very weak: $D_{ee} \ll D_{ii}$.

Implications of a Gap-Junction Syncytium

The inclusion of nearest-neighbor diffusion terms transforms the mean-field cortical model into a set of reaction-diffusion equations similar to those seen in nonlinear chemical dynamic systems (e.g., Brusselator). Since inhibitory diffusion strongly dominates excitatory diffusion, conditions are favorable for the emergence of a Turing instability (Turing 1952) leading to the spontaneous formation of spatially organized patterns of neural activity (see Fig. 2).

This Turing spatial instability can interact with a Hopf temporal instability arising from a slowing of the inhibitory responsiveness at GABA chemical synapses, producing spatiotemporal patterns that may underlay the slow activity modulations seen in functional MRI recordings of the default background state of the resting cortex (Steyn-Ross et al. 2009). Reduction of $i-i$ gap-junction diffusivity weakens the Turing instability, thus allowing GABA-mediated Hopf oscillations to

equally spaced points down the midline of the grid. *Right*: bird's-eye view of Q_e activity after 4 s. Grid resolution is 240×240 , representing a 25×25 -cm cortical sheet. *Color bar* shows firing rate in spikes/s (see Steyn-Ross et al. (2013) for model details and computer codes)

dominate, predicting global seizure in the limit of strongly suppressed inhibitory diffusion (Steyn-Ross et al. 2012). However, the role of gap junctions in seizure initiation and spread is controversial (Voss et al. 2011), with some researchers reporting seizure suppression with blockage of gap junctions (e.g., Carlen et al. 2000; Jin and Chen 2011), while others find that blockers increase seizure propensity (Yang and Ling 2007; Jacobson et al. 2010).

Nonlinear Turing–Hopf interactions may also be important for the genesis of the large, irregular ~1-Hz slow oscillations that characterize the unconsciousness of deepest slow-wave sleep and of drug-induced general anesthesia (Steyn-Ross et al. 2013).

Gating Current

David C. Sterratt

School of Informatics, University of Edinburgh,
Edinburgh, UK

Definition

Gating current is the component of the neuronal transmembrane current due to the movement of charges attached to voltage-gated ion channels.

Detailed Description

Physical Basis

The proteins making up ion channels are arranged into subunits, which are further organized into segments. About a third of the amino acid residues in the S4 segments of voltage-gated ion channels are positively charged arginine and lysine. These gating charges are acted on by the electric field across the membrane, with the force changing the stability of ion channel conformations. The movement of the gating charges perpendicular to the membrane during conformation changes is the gating current. This is distinct from the ionic current, the current due to ions flowing through the channel pore.

The theory of ion channels opened and closed via gating charges was postulated by Hodgkin and Huxley (1952), although they used the term “gates” rather than “ion channels.” They predicted that gating current associated with a channel opening will flow just before the ionic current starts to flow through the newly opened channel.

Measurement

Gating current was first measured in the 1970s (Armstrong and Bezanilla 1973). To measure the relatively small gating current, the ionic current has to be reduced, either by using channel blockers or reducing the concentration of permeant ions, and multiple recordings had to be averaged. During a depolarizing voltage step (Fig. 1), the gating current is outward since the positively charged residues are moving outward. As predicted by Hodgkin and Huxley, the gating current leads the ionic current.

Equivalent Gating Charge

The equivalent gating charge is the integral of the gating current that flows when the ion channel moves from the closed to open state. The equivalent gating charge gives the number of charges that would have to move all the way across the membrane when an ion channel opens or closes.

Gating Current, Fig. 1 Measurement of sodium gating current in squid axon by Armstrong and Bezanilla (1973). The *upper trace* is the gating current averaged over 2000 presentations of a voltage step from -70 to 0 mV. This is measured in artificial seawater in which sodium has been replaced by the impermeant ion Tris and potassium by cesium ions, which are impermeant. The *lower trace* is the ionic current seen in artificial seawater containing sodium. The gating current is seen to lead the sodium current. (Reproduced by permission from Macmillan Publishers Ltd: Nature 242, 459–461 ©1973. Note: permission is needed from Macmillan, publishers of Nature)

In principle, the equivalent gating charge could be made up of many charges moving a fraction of the transmembrane distance, but in fact a number of charged residues on the S4 segment of voltage-gated channels do move across the whole membrane (Hille 2001).

On the basis of the steepness of the activation curve of squid sodium channels, Hodgkin and Huxley (1952) predicted that the equivalent gating charge was around six elementary charges. This prediction is derived by considering the two components of the work required to move a gate (see ► “Hodgkin-Huxley Model”) from its closed position to its open position for a given membrane potential V :

- w , the work required were there no electric field (i.e., if $V = 0$)
- $-z_g e V$, the work required to move z_g equivalent gating charges, each with elementary charge e , across the membrane

From Boltzmann's principle, at equilibrium the ratio of the probability O of a gate being the open position to the probability C of it being in the closed position is

$$\frac{O}{C} = \exp(-(w - z_g eV)/k_B T) \quad (1)$$

where T is the temperature in kelvin and k_B is Boltzmann's constant. Given that $O + C = 1$, the fraction of gates in the open position is

$$O = \frac{1}{1 + \exp((w - z_g eV)/k_B T)} \quad (2)$$

This is a sigmoid curve, and by fitting it to the data for the open probability for the sodium m gate, Hodgkin and Huxley determined that $z_g \approx 6$.

Modern estimates of the equivalent gating charge are in the range of 12–16 elementary charges per potassium channel, 8–15 charges per calcium channel, and around 12 charges per sodium channel (Hille 2001). The equivalent gating charge is thus much smaller in magnitude than the typical number of ions that flow through a channel pore during an action potential or post-synaptic current.

Applications for Computational Neuroscience

The gating current is usually negligible compared to ionic currents and therefore tends not to be modelled explicitly. However, gating current recordings can be used to make inferences about the structure of ion channels. For example, recordings of gating currents from squid giant axon sodium channels do not follow the form predicted by Hodgkin and Huxley (1952) and therefore lead to a more complex model of the channel, in which activation occurs in several steps (Patlak 1991; Hille 2001).

Definition

Point process-generalized linear model. An adaptation of the generalized linear model framework to point processes using local Bernoulli or local Poisson models to analyze the relationship between neural spiking activity and relevant covariates such as putative stimuli and spike history.

Detailed Description

Most systems neuroscience experiments entail applying a stimulus and measuring the response which is commonly the spiking activity of one or more neurons (Brown et al. 2004; Paninski 2004; Truccolo et al. 2005; see entries ► “Spike Train,” ► “Spike Train Analysis: Overview”). The typical objective of the experiment is to define how spiking activity in a given brain area changes in response to the stimulus under a range of different conditions. From a statistical standpoint, this type of experimental design requires a regression model in which the observations can be spiking activity and the regressors can be the stimulus and any other relevant covariates. The generalized linear model (GLM) provides such a framework.

The standard linear regression model assumes observations with Gaussian errors. The GLM is an extension of the regression model to observations from any probability model in the exponential family (McCullagh and Nelder 1989). The exponential family includes many of the probability models commonly used in statistical analyses such as the Gaussian, Bernoulli, binomial, Poisson, gamma, and inverse Gaussian (DeGroot and Schervish 2012). The GLM is constructed by writing the exponential family model in canonical form and expressing the natural parameter as a linear function of the covariates. For example, the natural parameters are μ for the Gaussian, $\log \lambda$ for the Poisson, and $\log[p/(1 - p)]$ for the Bernoulli and the binomial. Relating the natural parameter to the regressors as a linear function defines the natural link for the GLM. The GLM offers several appealing features. Computation of the maximum likelihood estimate of the parameters can be carried out efficiently using iteratively reweighted least squares. For the Gaussian linear model, the iteration converges in one step to the exact least squares solution. The sum of squares in the standard analysis of variance generalizes in the GLM framework to the deviance which equals $-2 \times \log$ of the maximized likelihood function.

Brillinger showed that by modeling a neural spike train recorded a stimulus response experiment as a point process defined in terms of its conditional intensity function then GLM framework could be adapted to analyze this class of data

(Brillinger 1988). A point process is a binary (0–1) process observed in continuous time. In a small time interval, the product of the conditional intensity function times the time interval defines the probability of an event, or a 1, in the small time interval conditional on the history of the point process up to that time (Brown et al. 2003; Daley and Vere-Jones 2003). The conditional intensity function is therefore a history-dependent generalization of the rate function of Poisson process. In this way, a point process is a generalization of a Poisson process that allows history dependence, and like an inhomogeneous Poisson process, dependence on other covariates as well. The conditional intensity function is chosen as the quantity to model because it completely characterizes the point process. An alternative would be to model the interspike interval distribution. Use of the conditional intensity function is more flexible. Moreover, it is easy to show that the conditional intensity function specifies the interspike interval distribution and vice versa (Truccolo et al. 2005; Brown et al. 2003).

To apply the GLM framework to a neural spike train analysis, the spike train is modeled as a point process in which either the log of the conditional intensity function or the logit of the conditional intensity function times a small time interval is expressed as a linear function of the covariates of interest (Truccolo et al. 2005; Brillinger 1988). Time is discretized into non-overlapping mutually exclusive subintervals so that any subinterval contains at most one observation which is a 1 if there is a spike or a 0 if there is no spike. Each subinterval then defines a local Bernoulli model or a local Poisson model with only a 0 or 1. A Taylor series analysis of the local Bernoulli model for sufficiently small subintervals shows that it is equivalent to the local Poisson model. The joint distribution of the neural spike train data or, equivalently, the likelihood function of the model parameters is given by the product of the conditional probabilities of a spike or no spike defined by the local Bernoulli or the local Poisson model. For this reason, the data may be highly dependent, yet the likelihood function resembles the likelihood function of a product of Bernoulli or a product of Poisson random variables. Hence, by formulating a point process model in terms of a

conditional intensity function in discrete time, the Bernoulli or Poisson GLM can be used to fit a regression model relating the neural spiking activity to any covariates of interest, such as a putative stimulus or spiking history. This approach to neural spike train data analysis is termed point process GLM framework.

Berman, who also proposed the point process GLM framework (Berman and Turner 1992), suggested that goodness of fit for these models could be assessed using the time-rescaling theorem, which states that integrating the conditional intensity function between spike times transforms the interspike intervals into independent exponential random variables with rate 1 (Berman and Turner 1992; Berman 1983; Brown et al. 2002). To evaluate goodness of fit, the exponential structure in the transformed interspike intervals can be assessed using Kolmogorov-Smirnov plots (Berman and Turner 1992; Berman 1983; Brown et al. 2002; Ogata 1988). Independence can be assessed approximately by transforming the putative exponential or uniform random variables to Gaussian random variables and analyzing the autocorrelation function (ACF) (Czanner et al. 2008). If the autocorrelation function is not appreciably different from zero, as assessed by common ACF confidence interval formula, then we can infer that the original transformed interspike (putative exponential) intervals are approximately independent up to the order of the ACF that was analyzed.

The GLM can be used to analyze ensemble neural spiking activity to account of interactions among neurons in the ensemble and addition to any relevant covariates (Chornoboy et al. 1988; Okatan et al. 2005; see entry ► [“State-Space Models for the Analysis of Neural Spike Train and Behavioral Data”](#)). The GLM framework can be used to conduct Granger causality analyses for neural spike trains (Kim et al. 2011; see entries ► [“Correlation Analysis of Parallel Spike Trains,”](#) ► [“Dynamic Causal Modelling with Neural Population Models,”](#) ► [“Information Geometry as Applied to Neural Spike Data”](#)). Multivariate model extensions of the GLM using log linear models (Kass et al. 2011; Shimazaki et al. 2012) or simultaneous event multivariate point process (SEMPP) (Ba et al. 2014) models to analyze

synchrony in ensembles of neural spike trains at an arbitrary time resolution are now being developed (see entries ► [“Applications of Information Theory to Analysis of Neural Data,”](#) ► [“Information Measures of Redundancy and Synergy in Neural Activity”](#)). The SEMPP models use a marked point process representation to simulate ensemble neural spiking activity and can be fit using the multinomial extension of the iteratively reweighted least squares algorithm (Ba et al. 2014).

GEneral NEural Simulation System

Definition

GENESIS (The *GEneral NEural Simulation System*) is a simulation environment for constructing realistic models of neurobiological systems at many levels of scale including subcellular processes, individual neurons, networks of neurons, and neuronal systems (Wilson et al. 1989; Bower 1992; Bower and Beeman 2006; Beeman 2013). First released to the public in July 1990, it was one of the first simulation systems specifically designed for modeling nervous systems and also one of the first open-source software projects in computational biology. As a consequence, the GENESIS software system has benefited from many different contributors and has been responsible for many technical innovations and advancements.

Detailed Description

GENESIS is written in C and was originally developed for UNIX platforms (Wilson et al. 1989), although it now also runs under Mac OS and with Windows under the Cygwin environment. Originally developed in the author's laboratory at Caltech, the system was first released in June of 1988 in association with the first annual Methods in Computational Neuroscience Course at the Marine Biological Laboratory in Woods Hole, MA and then released as full source code to the public via anonymous FTP in July 1990. GENESIS version 2.0 was released in August 1995, with the latest update (version 2.3) released in May 2006 (available through the web site <http://sourceforge.net/projects/genesis-sim>). GENESIS Version 3.0 (G-3) is currently in beta release (<http://genesis-sim.org>) and represents a backwards compatible but complete restructuring of the software system.

From the outset, GENESIS design has predicated on several assumptions regarding computational neuroscience. These include: (1) the construction of computer models based on actual anatomy and physiology would be essential to understanding the computational organization of the nervous system (Bower 1991b, 1992, 2005, 2013; Bower and Beeman 2007);

(2) understanding nervous system function would depend on being able to construct and link models at many different levels of biological scale (Bower 1991a). (3) growth of the modeling system would depend on the ability of individual modelers to develop and share model features and components; (4) the system should be as machine independent as possible; (5) successful use would depend on a graphical interface supporting users with a range of computer expertise (Uhley et al. 1989; Bhalla 1998); (6) considerable time, effort, and resources would need to be committed to user support; and (7) in order to build modeling expertise within the neuroscience community GENESIS should support use in education as well as research (Fig. 1 from Bower and Beeman 1994).

The commitment of the GENESIS project to educational use is reflected in its first release in the inaugural year of the Methods in Computational Neuroscience course at the Marine Biological Laboratory in Woods Hole, MA, as well as in

subsequent courses offered in Europe, Asia, and Latin America. The tutorials developed for those courses provided the basis for “The Book of GENESIS” published in two editions (Bower and Beeman 1994, 1998). That book (now available as a free download: <http://www.genesis-sim.org/GENESIS/bog/bog.html>), was written both to support undergraduate and graduate education in computational neuroscience as well as an introduction to modelers interested in using GENESIS for research.

The development of educational tutorials has continued, with web-based tutorials for both GENESIS 2.3 and G-3. The GENESIS Documentation Home Page (<http://genesis-sim.org/userdocs/documentation-homepage/documentation-homepage.html>) contains links for documentation and tutorials for both versions. The “Ultimate GENESIS Tutorial Distribution” (<http://genesis-sim.org/GENESIS/UGTD.html>) is a complete self-paced GENESIS modeling course, combined with GENESIS 2.3 distributions and installation instructions.

GENESIS, the GEneral NEural Simulation System, Fig. 1 Original cover for the Book of GENESIS (first edition) (used with permission Bower and Beeman 1994)

It provides an easy way to get everything for GENESIS 2.3 by downloading a single package.

As one of the first neural simulations systems, the GENESIS project has also had a long history of innovation in the application of numerical simulation techniques to computational neuroscience. For example, GENESIS was one of the first open software systems in computational biology (Wilson et al. 1989); was the first simulation system supporting realistic modeling across a wide range of scales from large scale networks (Wilson and Bower 1989, 1991, 1992) to single neurons (De Schutter and Bower 1992) to subcellular (Blackwell et al. 2013); has fostered the application of new numerical simulation techniques for neurobiological modeling (Vanier and Bower 1999; Eichler West et al. 1997), was the first simulation system to promote quantifying parameter searches and modeling results (Bhalla and Bower 1993; Eichler West et al. 1997; Vanier and Bower 1996, 1999; Baldi et al. 1998); was one of the first computational modeling systems to be adapted for use on parallel computers (Bower et al. 1988; Nelson et al. 1989; De Schutter and Bower 1992), and was the first system to link geographically remote computers together in a single neuronal simulation (Leigh et al. 1993). The GENESIS project was also the first to propose standards against which to judge the speed and reliability of neural simulators (Bhalla et al. 1992, 1993), and was one of the first simulation systems to adopt the Python object-oriented declarative scripting language (Vanier 2001 thesis). From a user perspective, the GENESIS group was the first to develop a graphical interface specifically for use by neurobiologists for modeling (Uhley et al. 1990; Bower and Hale 1991; Forss et al. 1999), was the first to use virtual reality visualization techniques (Leigh et al. 1995), and was the first to use the Internet in support of intercommunication between neurobiologists and their modeling efforts (Leigh et al. 1995). The GENESIS project has pioneered the development of tools to convert neurobiological data into usable forms for models (West et al. 1997) and also pioneered the use of modeling databases as sources of biological data (Hucka et al. 2002). From the outset, the

GENESIS development group has also promoted and supported efforts to provide interoperability between neural simulators (Beeman and Bower 2004; Cannon et al. 2007; Crook et al. 2013), beginning with the Modelers Workspace project (www.modelersworkspace.org), which drafted and promoted the first markup language for realistic neural modeling (Goddard et al. 2001). That initial effort subsequently provided the foundation for the development of NeuroML (Crook et al. 2007; Gleeson et al. 2010) (<http://neuroml.org>), which, in turn, has fostered the development of simulator interoperability tools including neuroConstruct (Gleeson et al. 2007).

A Modeler's View of GENESIS

From the standpoint of a modeler who is implementing a neural model with GENESIS version 2.3 or 3.0, the object oriented interface presented to the user is one of its most useful features. The design of GENESIS simulations and their Graphical User Interfaces are based on a “building block” approach. Simulations are constructed from modules that receive inputs, perform calculations on them, and then generate outputs. Model neurons are constructed from compartments to which are added variable conductance ion channels forming multi-compartmental neurons of any desired level of complexity. Neurons can then be linked together to form neural circuits of any size. A high level scripting language is used to recognize commands for combining these objects into neuron, network or system level models, and to optionally create a custom GUI for the simulation, as shown in Figs. 2 and 3. GENESIS has also been adapted to modeling subcellular structures as well (Blackwell et al. 2013).

This object-oriented approach is central to the generality and flexibility of the system, as it allows modelers to easily exchange and reuse models or model components. In addition, it makes it possible to extend the functionality of GENESIS by adding new commands or simulation components to the simulator, without having to modify the GENESIS base code itself.

GENESIS, the GEneral NEural Simulation System, Fig. 2 A GUI for running a network simulation scripted with GENESIS 2.3

GENESIS 3 (G-3)

After the release of GENESIS 2.3, development efforts shifted to re-implementing GENESIS as a true twenty-first century simulation system (Beeman 2013), while preserving the most desirable features of the present version. This effort, known as GENESIS 3.0, or G-3, is intended to take simulator interoperability as well as flexibility in simulator design, development and use to a new level. With G-3 the GENESIS development group has completely restructured the historical monolithic core of GENESIS and reimplemented the system as a collection of independent software components. Based on the modular CBI architecture (Cornelis et al. 2012a), G-3 consists of a set of largely independent components which can be

used either individually or in combination to perform the functions desired in running a particular simulation. Keeping with the original design objectives for the GENESIS project, this modularization considerably enhances the ability to run models across different levels of biological scale, and greatly facilitates interactions between those levels.

By separating user-specified model description from their machine level implementation, G-3 simplifies the development of new mathematical solvers and other run-time software components. This separation also allows for an assessment of model structure independent of its algorithmic implementation, providing among other advantages, the opportunity to build a new form of model-based publication system (Cornelis et al.

GENESIS, the General NEural Simulation System, Fig. 3 View of the network membrane potential and summed excitatory post-synaptic currents produced by

the simulation in Fig. 1. This was produced by the G-3 Python 'netview' tool

2010). Through its modularization G-3 allows simulations to be run locally and/or distributed over networks (Coop et al. 2010). The use of multiple parsers for scripting simulations allows G-3 to maintain backwards compatibility with GENESIS 2.3, and to support the use of scripts written in modern scripting languages such as Python. The modular CBI architecture also provides a template for interacting with and even incorporating other software systems (Cornelis et al. 2012b). As the first truly modular neural simulation system, G-3 provides a plastic and extensible framework that is designed to represent the next step in evolution of simulation systems for computational neuroscience (Brette et al. 2007; Beeman 2013).

[Stochastic Simulation Algorithm \(SSA\)](#)

Definition

The Gillespie Algorithm, also known as the Stochastic Simulation Algorithm (SSA), is a computer-oriented procedure for simulating the changes in the molecular populations of chemical species in a chemically reacting system. The algorithm requires the reactant molecules, typically solute molecules in a sea of many much smaller solvent molecules, to be dilute and well-mixed throughout the containing volume. In contrast to the traditional differential equations of chemical kinetics, which imposes not only those requirements but also the requirement that the molecular populations be very large, the SSA simulates the occurrence of individual reaction events in a way that properly reflects their inherent randomness. That randomness is often important for the relatively low molecular populations that commonly occur in cellular systems.

Since the middle of the nineteenth century, ordinary differential equations (ODEs) have been the standard mathematical tool for modeling the way in which molecular populations in chemically reacting systems evolve in time. The broad success of that modeling strategy is, however, a little surprising: ODEs prescribe a behavior that is

continuous and deterministic, yet molecules come in whole numbers, and they react chemically in ways that are largely random. Those features can be important when the molecular populations of some key reactants are relatively small, as in a biological cell.

The stochastic simulation algorithm (SSA), also known as the Gillespie algorithm (Gillespie 1976, 1977), is a procedure for numerically modeling the evolution of certain chemically reacting systems that takes proper account of the system's inherent discreteness and randomness. In the limit of infinitely large molecular populations that discreteness and randomness become imperceptible, and the SSA reduces to the ODEs of conventional deterministic chemical kinetics (Gillespie 2009a; Gillespie et al. 2013). Since those ODEs are thus a limiting approximation of the SSA, we cannot use them to derive the SSA. An honest derivation of the SSA must look to molecular physics to see how chemical reactions actually occur, and then adopt a mathematical formalism that accurately describes that physics.

The system of concern here is a collection of molecules of N chemical species $S_1, \dots, S_N$ which are confined to some volume Ω at some temperature T and which are undergoing M chemical reactions $R_1, \dots, R_M$. The goal is to numerically simulate the time evolution of $\mathbf{X}(t) \equiv (X_1(t), \dots, X_N(t))$, where $X_i(t)$ is the (integer) number of S_i molecules in Ω at time t . Importantly, each reaction R_j is assumed to be “elemental,” in that its occurrence as a physical event is effectively instantaneous on the time scale of interest. In cellular chemistry such reactions will practically always be one of two types: either unimolecular, in which a molecule suddenly experiences internal changes that alter its chemical character; or bimolecular, in which a chemical change is immediately triggered by the collision of two molecules. Trimolecular and reversible reactions in cells practically always occur as a series of two or more elemental reactions.

The unimolecular reaction $R_j : S_i \rightarrow \dots$ is inherently nondeterministic, usually for quantum mechanical reasons; there is no deterministic rule that predicts when a given S_i molecule will so react. But molecular physics implies that

the probability that a given S_i molecule will undergo this reaction in the next infinitesimally small time dt can usually be written $c_j \cdot dt$, where c_j is some constant (independent of both t and dt) that depends on the microphysical properties of an S_i molecule. Summing the probability over all $X_i(t)$ S_i molecules in Ω at the current time t then allows us to conclude, by the adding law of probability, that $X_i(t) \cdot c_j dt$ is the probability that an R_j event will occur somewhere inside Ω in the next dt .

The bimolecular reaction $R_j : S_i + S_k \rightarrow \dots$ is more problematic. A relatively simple physics argument (Gillespie 1976) shows that if the reactant molecules comprise a well-mixed dilute gas, then the probability that a randomly chosen $S_i - S_k$ molecular pair will undergo this reaction in the next dt can be written $c_j \cdot dt$, where the constant c_j is an explicit function of the physical properties of the two molecules, the system temperature T , and the system volume Ω . This dilute gas result was later extended (Gillespie 2009b; Gillespie and Seitaridou 2012) to the more biologically relevant case in which the S_i and S_k molecules are solute molecules in a well-mixed dilute solution with many smaller chemically inert solvent molecules. The c_j for the solution case is given by a more complicated formula than the c_j for the gas case; however, both are inversely proportional to Ω (whereas the c_j for a unimolecular reaction is independent of Ω). Moreover, the solution phase c_j limits to the gas phase c_j when the sum of the diffusion coefficients of the S_i and S_k molecules is sufficiently large. Summing the single-pair bimolecular reaction probability $c_j dt$ over all distinct pairs of S_i and S_k molecules in Ω at the current time t gives $X_i(t)X_k(t) \cdot c_j dt$ for the probability that an R_j event will occur in the next dt when $k \neq i$, or $\frac{1}{2}X_i(t)(X_i(t) - 1) \cdot c_j dt$ if $k = i$.

Thus, at least for chemical systems in which the reactant molecules are dilute and well-mixed in a bath of many much smaller chemically inert molecules, there will exist for each elemental reaction R_j a function a_j of the current species populations $\mathbf{x} = (x_1, \dots, x_N)$ which is such that $a_j(\mathbf{x}) \cdot dt$ gives the probability that an R_j event will occur somewhere inside Ω in the next infinitesimal time interval $[t, t + dt)$. This function a_j is

called the propensity function for reaction R_j because it quantifies the propensity for R_j to fire. It has the form $a_j(\mathbf{x}) = c_j x_i$ for a unimolecular reaction, and the forms of either $a_j(\mathbf{x}) = c_j x_i x_k$ or $a_j(\mathbf{x}) = c_j x_i (x_i - 1)$ for a bimolecular reaction.

Propensity functions are closely related to the “reaction rates” of deterministic chemical kinetics; however, the latter are derived from the former, not vice versa. Whether propensity functions exist for other kinds of cellular environments, such as where the reactant molecules are not dilute or where they move by active mechanisms along actinic pathways, and if so what forms such propensity functions take, are questions that can be answered only by a careful analysis of the underlying molecular physics of the specific situation.

Each reaction channel R_j is mathematically defined not only by its propensity function $a_j(\mathbf{x})$ but also by its state-change vector $\mathbf{v}_j \equiv (v_{1j}, \dots, v_{Nj})$. Here, v_{ij} is the (signed integer) change in the molecular population of species S_i caused by one R_j event, i.e., an R_j reaction induces the state change $\mathbf{x} \rightarrow \mathbf{x} + \mathbf{v}_j$. The SSA asks, and then answers, the following question: Assuming propensity functions exist, then given the system is in state $\mathbf{x}$ at the current time t , at what time $t + \tau$ will the next reaction in the system occur, and which R_j will that next reaction be? Since the probabilistic character of the propensity functions implies that τ and j must be random variables, the answer to this question can be supplied only by the joint probability density function (PDF) of τ and j . That function is denoted by $p(\tau, j | \mathbf{x}, t)$, and it is defined so that $p(\tau, j | \mathbf{x}, t) \cdot d\tau$ gives the probability that the next reaction event in the system will occur in the infinitesimal time interval $[t + \tau, t + \tau + d\tau)$ and will be a reaction R_j . From the definition of the propensity function, it can be proved using only the laws of probability that (Gillespie 1976)

$$p(\tau, j | \mathbf{x}, t) = e^{-a_0(\mathbf{x})\tau} a_j(\mathbf{x}),$$

where $a_0(\mathbf{x}) \equiv \sum_{k=1}^M a_k(\mathbf{x})$. The SSA is thus the following computational procedure:

1. In state $\mathbf{x}$ at time t , evaluate (as necessary) $a_1(\mathbf{x}), \dots, a_M(\mathbf{x})$ and their sum $a_0(\mathbf{x})$.

2. Generate two random numbers τ and j according to the above joint PDF.
3. Actualize the next reaction by replacing $t \leftarrow t + \tau$ and $\mathbf{x} \leftarrow \mathbf{x} + \mathbf{v}_j$.
4. Record $(\mathbf{x}, t)$. Return to step 1, or else end the simulation.

Step 2 of the SSA can be implemented using any of several different exact “methods.” Two such methods were presented in Gillespie (1976): the direct method, which follows from a straightforward application of the well-known inversion Monte Carlo generating technique to the above joint PDF, and the first reaction method, which is less straightforward but nonetheless exact. The direct method is usually more efficient, and it goes as follows: Draw two unit-interval uniform random numbers u_1 and u_2 and take

$$\tau = \frac{1}{a_0(\mathbf{x})} \ln \left(\frac{1}{1 - u_1} \right),$$

$j =$ the smallest integer satisfying $\sum_{k=1}^j a_k(\mathbf{x}) > u_2 a_0(\mathbf{x})$.

Figure 1 shows the results of two SSA runs for the simple reaction $S \rightarrow \emptyset$ obtained using this method. Other exact methods of implementing step 2 have been developed that offer certain computational advantages in special situations. Notable among these are the next reaction method (Gibson and Bruck 2000), the optimized direct method (Cao et al. 2004), the sorting direct method (McCollum et al. 2006), the modified next reaction method (Anderson 2007), and the composition-rejection method (Slepoy et al. 2008). A critique of the efficiencies of these and several other methods is given in (Mauch and Stalzer 2011).

The strength of the SSA is also its weakness: simulating the occurrence of every reaction event one at a time, no matter what method is used to implement step 2, often requires too much computer time. One approximate strategy for getting around that problem is a procedure called tau-leaping (Gillespie 2001), a much improved version of which is described in (Cao et al. 2006) and (Gillespie 2008). Tau-leaping solves some, but

Gillespie Algorithm for Biochemical Reaction Simulation, Fig. 1 The red and blue stair-step curves show the results of two independent runs of the SSA for the chemical reaction $S \xrightarrow{c} \emptyset$ with $c = 1$ and $x_0 = 100$. In this simple one species/one reaction example, $a(x) = x$ and $\nu = -1$. After each generation of a value for τ using the direct method formula, t was increased by τ and the population was decremented by 1. Note that the trajectory thus produced

is complete, since the population stays constant between successive reactions. The smooth black curve is the solution $x_0 \exp(-ct)$ of the traditional ODE for this reaction, $dX(t)/dt = -cX(t)$. It shows the average of infinitely many trajectories; however, any single trajectory will always have the discrete-stochastic character of the two colored curves

not all, of the slowness problems of the SSA. It is also important because it provides a logical bridge between the SSA and the ODEs of traditional chemical kinetics, since it reduces to those ODEs in the limit of an infinitely large system (Gillespie 2009a; Gillespie et al. 2013).

Relaxing the “well-mixed” requirement of the SSA requires expanding the definition of the system’s state to include information on where the reactant molecules are inside Ω . One way of doing that is to imagine Ω to be subdivided into K identical subvolumes or voxels $\Omega_1, \dots, \Omega_K$, which are small enough that the well-stirred condition holds inside each Ω_k . The M nominal reactions $\{R_j\}$ are then replaced by the MK reactions $\{R_{jk}\}$, where R_{jk} is reaction R_j inside voxel Ω_k . The propensity function for R_{jk} is a_j , but now referred to as Ω_k and regarded as a function of $\mathbf{x}_k = (x_{1k}, \dots, x_{Nk})$, where x_{ik} is the current number of S_i molecules inside Ω_k . And the state-change vector

for R_{jk} is $\boldsymbol{\nu}_j$, but now confined to the space of $\mathbf{x}_k$. Diffusion of a single S_i molecule from voxel Ω_k to an adjacent voxel Ω_l is modeled as a “diffusive transfer reaction” R_{ikl}^d whose propensity function is $\kappa_i x_{ik}$, where κ_i is a constant chosen to agree with the diffusion equation (Gillespie and Seitaridou 2012), and whose state-change vector decreases x_{ik} by 1 and increases x_{il} by 1. Since diffusion between voxels is mathematically modeled in the same way (using propensity functions) as the chemical reactions inside voxels, the system can be simulated using the SSA with the following straightforward replacements: the N -dimensional state vector $\mathbf{x} = \{x_i\}$ is replaced by the NK -dimensional state vector $\{x_{ik}\}$, and the M reactions $\{R_j\}$ are replaced by the MK chemical reactions $\{R_{jk}\}$ plus the $2NB$ diffusive transfer reactions $\{R_{ikl}^d\}$, where B is the total number of boundary surfaces between adjacent subvolumes.

Goldman-Hodgkin-Katz Equations

David C. Sterratt
School of Informatics, University of Edinburgh,
Edinburgh, UK

Synonyms

[GHK current equation](#); [GHK voltage equation](#)

Definition

There are two Goldman-Hodgkin-Katz (GHK) equations: the GHK voltage equation and the GHK current equation. The GHK voltage equation gives the membrane potential expected to result from multiple ion species at differing concentrations on either side of the membrane. The GHK current equation gives the transmembrane current of an ion species expected at a given membrane potential for a given concentration of the ion on either side of the membrane. Both equations are derived from the Nernst-Planck equation with a constant field assumption in the membrane. This assumption is not generally true in ion channels, but the equations are a useful approximation for neuronal modelling.

Detailed Description

Physical Basis

The GHK equations apply when one or more ion species exist on both sides of a membrane permeable to them. The electrical and diffusive influences on each ion are not necessarily at equilibrium, and thus there can be a net flow of

Goldman-Hodgkin-Katz Equations, Fig. 1 I - V characteristics computed from the GHK current equation. (a) Calcium at an intracellular concentration of 10^{-4} mM and extracellular concentration of 10 mM. The dotted vertical

line indicates the equilibrium potential calculated from the Nernst equation. (b) Potassium at an intracellular concentration of 400 mM and an extracellular concentration of 20 mM.

each ion species through the membrane. This is in contrast to the situation in which there is an equilibrium between electrical and diffusive influences on an ion species, in which case the Nernst equation applies. The GHK equations are derived from a theory in which it is assumed that the electric field in a membrane is constant. This is not generally true (Hille 2001), but the GHK equations are nevertheless a good approximation for describing current flow through ion channels.

The GHK Current Equation

The GHK current equation (Goldman 1943; Hodgkin and Katz 1949) for an ion species X gives the per-unit area current I_X carried by that ion as a function of the permeability P_X of the membrane to the ion, the membrane potential V , the intracellular and extracellular concentrations of the ion $[X]_{\text{in}}$ and $[X]_{\text{out}}$, and the valency z_X of the ion:

$$I_X = P_X z_X F \frac{z_X F V}{RT} \left(\frac{[X]_{\text{in}} - [X]_{\text{out}} e^{-z_X F V / RT}}{1 - e^{-z_X F V / RT}} \right)$$

where F is Faraday's constant, R is the molar gas constant, and T is the temperature in kelvins. By convention, a positive current is defined as an outward flow of positive charge and a negative current as an inward flow of positive charge.

A plot of the GHK calcium current versus the membrane potential (an I - V characteristic) is

shown in Fig. 1a. When the membrane potential is equal to the equilibrium potential for calcium, as given by the Nernst equation, the current is equal to zero. When the membrane potential is less than the equilibrium potential, the current is inward (negative), and when the membrane potential exceeds the equilibrium potential, it is outward (positive). The inward currents are much greater than the outward currents, demonstrating inward rectification. The greater the difference between the intracellular and extracellular concentrations, the greater the degree of rectification. An I - V characteristic for potassium (Fig. 1b) shows a much weaker degree of outward rectification. Inward rectification occurs when the extracellular concentration of the ion exceeds the intracellular concentration.

The GHK Voltage Equation

The GHK voltage equation describes the equilibrium potential reached when multiple ion species exist in solution around a membrane that is permeable to each species. It is derived from the GHK current equations by computing the value of the membrane potential at which the sum of all ionic currents across the membrane is zero. Note that this does not mean that each ion species is in equilibrium, since the membrane potential is likely not to correspond to the equilibrium potential of any one species.

For a membrane permeable to sodium, potassium, and chloride ions, the GHK voltage equation derived from the GHK current equations is

$$V = V_{\text{in}} - V_{\text{out}} \\ = \frac{RT}{F} \ln \frac{P_K[K^+]_{\text{out}} + P_{\text{Na}}[\text{Na}^+]_{\text{out}} + P_{\text{Cl}}[\text{CT}]_{\text{in}}}{P_K[K^+]_{\text{in}} + P_{\text{Na}}[\text{Na}^+]_{\text{in}} + P_{\text{Cl}}[\text{CT}]_{\text{out}}}$$

where P_K , P_{Na} , and P_{Cl} are the membrane permeabilities to K^+ , Na^+ , and Cl^- , respectively. Note that within the logarithmic term the outside and inside concentrations of cations (K^+ and Na^+ in this case) are on the numerator and denominator, respectively, whereas it is the other way round for the anions (Cl^- this case). The form of this equation is possible because all the ions are monovalent. It is also possible to derive a GHK voltage equation that includes monovalent and divalent ions, but its form is more complex, as it involves the solution of a quadratic equation.

Derivation

Hille (2001) and Johnston and Wu (1995) present accessible derivations of the GHK current equation.

Gravity Analysis of Parallel Spike Trains

George L. Gerstein

Department of Neuroscience, University of Pennsylvania, Philadelphia, PA, USA

Definition

The gravity representation is a mapping of the spiking activity of N neurons into a mechanical model. The method originated with an effort to measure plant similarity (Wright 1977). In the present context, each neuron is represented by a particle moving in an N -dimensional space. Action potentials produce transient “charges” on the particle which corresponds to the neuron which fired. The particles move according to forces caused by attraction or repulsion of the charges; any near-coincidence structure in the neuronal firing is transformed into aggregation of the model particles. The speed and dynamics of the clustering process can be interpreted in terms of the dynamics of the underlying neuronal interactions. The gravity representation is mostly useful as a screening stool to identify interacting neurons that should be further studied.

Detailed Description

In the N -dimensional space, the initial position of the i -th particle along the j -th axis is given by

$$\mathbf{x}_i^j = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases} \quad (1)$$

The charge on particle i at time t is given by

$$q_i(t) = \sum_k K(t - T_k) - \lambda_i \quad (2)$$

Here T_k are the times of the spikes fired by this cell, and $K(t)$ is a kernel function which is convolved with the spike train. The kernel function is assumed to have unit area and is frequently taken as a simple decreasing exponential with a time constant τ .

Particle positions are adjusted according to the pairwise attractions between particles. Thus, using a discrete time step of δt , the position update rule is

$$\mathbf{x}_i(t + \delta t) = \mathbf{x}_i(t) + \kappa \delta t \sum_{j \neq i} Q_{i,j} \frac{\mathbf{x}_j - \mathbf{x}_i}{|\mathbf{x}_j - \mathbf{x}_i|} \quad (3)$$

where

$$Q_{i,j} = q_i q_j \quad (4)$$

Note that this is an update rule that has velocity rather than acceleration proportional to attractive force. In real physical systems, this would only occur over a narrow range of conditions for particles moving in a viscous medium.

With the above equations, there will be aggregation of the particles representing approximately synchronously firing neurons, while particles representing independent neurons will remain roughly near their starting points in the N -dimensional space. Such aggregations cannot be directly visualized because they are N -dimensional and their detection is generally a problem in cluster analysis. However, we have found several simple and useful graphical methods that reduce the dimensionality for visualization (Gerstein et al. 1985; Dayhoff 1994; Gerstein 2010).

A useful visualization method graphs the time course of the distance between particles for each pair of particles. The distance between any two particles in the N space is a vector quantity, but here we will consider only its magnitude. For N neurons there will be $N(N-1)/2$ intra-pair distance trajectories. The trajectories for pairs involving independent neurons will remain (noisily) at the initial distance value; trajectories for pairs involving synchronous neurons will slope downwards at rates related to the strength of the synchrony.

Projection of the N -dimensional system to a two-dimensional plane loses information, can produce spurious particle aggregation, and must be carefully checked against the pair distance data. However, such projection allows direct visualization of the development of the particle movements and their interpretation in terms of neuronal interactions. We have found a simple geometric projection convenient for small numbers of neurons (e.g., $N < 20$). Here the projection plane is determined by the centers of gravity of various particle combinations and hence is a dynamic rather than a fixed plane (Gerstein and Aertsen 1985).

Many variations of the basic gravity rules serve particular analysis purposes and can be found in the original literature (e.g., Baker and Gerstein 2000). One example is to use two different kernels for the “charge” on each particle, one for when the particle is being moved (i in Eq. 3) and the other for when the particle is one of the movers (j in Eq. 3). If these two kernels are, respectively, a falling exponential and a rising exponential, the i particle will move only when it represents a pre-synaptic neuron.

The greatest utility of the gravity representation is the identification of those neurons in an ensemble recording that are interacting (as evidenced by their timing relations) as illustrated, e.g., in Maldonado and Gerstein (1996), Lindsey et al. (1992, 1997), and Arata et al. (2000) and hence worthy of more detailed study. However, the basic method is limited in its ability to define the nature of the neuronal

interactions and the detailed diagram of the effective connectivities.

Hebbian Learning

Yoonsuck Choe

Engineering, Texas A&M University, College
Station, TX, USA

Definition

Hebbian learning is a form of activity-dependent synaptic plasticity where correlated activation of pre- and postsynaptic neurons leads to the strengthening of the connection between the two neurons. The learning principle was first proposed by Hebb (1949), who postulated that a presynaptic neuron A, if successful in repeatedly activating a postsynaptic neuron B when itself (neuron A) is

active, will gradually become more effective in activating neuron B. The concept is widely employed and investigated in both experimental and computational neuroscience.

Detailed Description

In this article, we will review computational formulations and theoretical bases of Hebbian learning and its variants. We will also briefly review neurobiological underpinnings of Hebbian learning. See Frégnac (2003), Gerstner and Kistler (2002), Shouval (2007), and Dayan and Abbott (2001) for a more in-depth review of this topic.

Basic Formulations

The formulation in this subsection closely follows that of Dayan and Abbott (2001). Consider a presynaptic neuron with activity x and a postsynaptic neuron with activity y connected by a synapse with weight (strength, efficacy) w , as shown in the figure below (Fig. 1). The activities and weights are commonly represented with positive real numbers.

The simplest formulation of Hebbian learning based on the above configuration results in the following weight update rule

$$\frac{dw}{dt} = \eta xy, \quad (1)$$

where the learning rate η is a small fixed positive value. This rule requires that both presynaptic and postsynaptic neurons are active in order to adjust the connection weight, thus faithfully implementing Hebbian learning.

When there are multiple input neurons feeding into a single output neuron (Fig. 2), all the incoming weights can be represented as a column vector $\vec{w}$, and averaging ($\langle \cdot \rangle$) over multiple input vectors,

Hebbian Learning, Fig. 1 A single presynaptic neuron connected to a single postsynaptic neuron

Eq. 1 can be written as the input correlation matrix (Q) times the weight vector.

$$\frac{d\vec{w}}{dt} = \langle \vec{x} \vec{x}^T \rangle \vec{w} = Q \vec{w}, \quad (2)$$

since $y = \vec{w}^T \vec{x}$. Thus, this learning rule is often called the “correlation-based rule.”

An obvious shortcoming of this approach is that the weight will increase (synaptic potentiation) without bound, since every time weight is updated, the value is incremented by a positive quantity. One quick way to overcome this problem is to impose thresholds θ_x and/or θ_y (see, e.g., Linsker 1988; for a review, see Frégnac 2003; Shouval 2007)

$$\frac{d\vec{w}}{dt} = \eta (\vec{x} - \vec{\theta}_x) (y - \theta_y), \quad (3)$$

so that neuronal activity falling below the threshold would result in a decrease in the synaptic weight (synaptic depression; see Stent 1973 for a discussion on such thresholding mechanisms). Note that when Eq. 3 is generalized to multiple inputs as in Eq. 2 and the thresholds are set to the mean input vector or the mean output value, the input correlation matrix Q is replaced by the input covariance matrix C (the “covariance rule”; see Sejnowski 1977). However, this kind of threshold mechanism alone (when the threshold is fixed) is not enough to prevent unchecked growth of the synaptic weight (Dayan and Abbott 2001).

Hebbian Learning, Fig. 2 Multiple presynaptic neurons connected to a single postsynaptic neuron

Preventing Unbounded Growth of the Synaptic Weight

There are two types of mechanisms to limit unbounded growth in synaptic weight: (1) adaptive threshold and (2) weight normalization.

A representative example of the adaptive threshold-based approach is the BCM (Bienenstock, Cooper, and Munro) rule (Bienenstock et al. 1982), where a variant of Eq. 3 is used ($\vec{\theta}_x = \vec{0}$), along with a threshold adaptation rule (on the postsynaptic threshold θ_y) that depends on the output activity y . Following the formulation in Dayan and Abbott (2001), we get

$$\frac{d\theta}{dt} = \eta_\theta (y^2 - \theta_y), \quad (4)$$

where η_θ is a fixed adaptation rate for the threshold update rule.

Weight normalization-based approaches basically impose constraints on synaptic plasticity (Miller and MacKay 1994; von der Malsburg 1973) and can be classified further into two types where (1) the sum of weights is kept constant or (2) the sum of squares of the weights (or the square root of it, i.e., the length of the weight vector) is kept constant. Such normalization can be done by simply updating all the weights based on the basic learning equation (Eq. 1) and then dividing all weights with the sum of weights or the sum of squared weights. Alternative implementations of these two types take a dynamic form, where the terms that are involved in weight normalization are directly built into the dynamic learning equation. In this context, the sum of weight-based normalization is also called subtractive normalization, and the sum of squared weight-based one called multiplicative normalization (Miller and MacKay 1994). The latter, which is based on a power series expansion of the division by sum of squared weights (length of weight vector, to be more precise) approach, leads to Oja's rule (once the higher order terms are dropped)

$$\frac{d\vec{w}}{dt} = \eta (y\vec{x} - y^2\vec{w}), \quad (5)$$

where the first term on the right-hand side ($y\vec{x}$) implements basic Hebbian learning, while the second term ($-y^2\vec{w}$) serves the normalization function (Oja 1982).

Theoretical Perspectives

Hebbian learning has been intensively analyzed for its theoretical, computational properties. The key question in this case is what kinds of optimization principles are implemented by the Hebb rule.

One of the earliest discoveries in this respect was made by Oja (1982), where the formulation in Eq. 5 was shown to converge to the first principal component of the inputs (the eigenvector of the input correlation matrix with the largest eigenvalue; also see Amari 1977). Subsequent analysis by Linsker (1988) showed that Hebbian learning can serve various optimization functions: (1) maximize the postsynaptic neuron's activity variance (cf. Oja 1982), (2) maximize variance in the postsynaptic neuron's activity while minimizing the variance due to processing noise, and (3) maximize information preservation between the presynaptic and postsynaptic neurons' activity (i.e., maximize the mutual information between the input and the output).

General learning algorithms such as self-organizing maps (SOM), Hopfield network, error backpropagation learning, temporal difference learning, and independent component analysis can also be interpreted under a Hebbian learning framework (see Kohonen 1993; Hopfield 1982; Xie and Seung 2003; Rao and Sejnowski 2001; Hyvärinen and Oja 1998, respectively).

Neurobiological Underpinnings

Hebbian learning has served as an important theoretical construct to guide experimental research. Efforts in this direction led to the discovery of long- and short-term synaptic plasticity that appears to embody a Hebbian principle, most notably in the hippocampus. A comprehensive

review of long-term synaptic plasticity (long-term potentiation, long-term depression) can be found in Bliss and Collingridge (1993), Dudek and Bear (1992), and a similar treatment of short-term plasticity (spike timing-dependent plasticity) in Caporale and Dan (2008). Here, we will briefly go over some of the main findings reviewed in these articles.

Long-term potentiation (LTP) refers to a prolonged increase in synaptic efficacy (weight) following high-frequency stimulation (Bliss and Collingridge 1993). The phenomenon was first discovered in the hippocampus, and the *N*-methyl-d-aspartate (NMDA) receptor, a subtype of glutamate receptor, is known to play a key role, as well as the intracellular Ca^{2+} concentration. Long-term depression (LTD), on the other hand, is a phenomenon where low-frequency stimulation leads to a prolonged decrease in synaptic efficacy (Dudek and Bear 1992). An interesting fact is that these phenomena seem to be governed by some type of activity threshold. These mechanisms, together, are believed to form the cellular basis of Hebbian learning (see Beggs 2000 for a statistical analysis of LTP and LTD and their relation to the BCM rule). Experimental findings also suggest how weight normalization could be done at these synapses: it has been shown that changes in the efficacy of a single synapse can have a scaling effect on other synapses in the same neuron. This mechanism is called homeostatic plasticity (see Turrigiano 1999 for a review). Finally, a spike timing-dependent mechanism that seems to embody Hebbian principles has been found, where the relative ordering of pre- and postsynaptic events leads to an asymmetric behavior – potentiation or depression – depending on the causal order of events. This is known as spike timing-dependent plasticity, and it is being actively investigated in relation to Hebbian learning (see Caporale and Dan 2008 for a review).

Applications of Hebbian Learning

Hebbian learning and similar mechanisms have found wide usage, including unsupervised learning tasks and modeling cortical development (see,

e.g., Miikkulainen et al. 2005). See McClelland (2006) for a discussion of applications of Hebbian learning in biological and psychological development.

Definition

Hierarchical models of the visual system are neural networks with a layered topology. The receptive fields of units (i.e., the region of visual space to which units respond) at one level of the hierarchy are constructed by combining inputs from units at a lower level. After a few processing stages, small receptive fields tuned to simple stimuli get combined to form larger receptive fields tuned to more complex stimuli. Such an anatomical and functional hierarchical architecture is a hallmark of the organization of the visual system. In feedforward networks, information flows in a bottom-up fashion – from lower to higher processing stages. In feedback networks, information is able to dynamically reenter processing stages via recurrent connections. Feedback connections can be broadly divided between horizontal or lateral connections within processing stages and top-down connections from higher onto lower processing stages.

Since the pioneering work of Hubel and Wiesel (1962), a variety of hierarchical models have been proposed, from relatively small-scale models of the primary visual cortex to very large-scale (system-level) models of object and action recognition, which account for visual processing in entire visual streams. The term “model of the visual system” is generally reserved for

architectures that are constrained in some way by the anatomy and the physiology of the visual system (with various degrees of realism). Deep convolutional networks are architecturally similar neural networks that have led to impressive results in a wide range of engineering disciplines, from computer vision to natural language processing, and artificial intelligence more broadly.

Detailed Description

The feedforward flow of visual information in the ventral stream of the visual cortex is carried by ascending projections from the retina, through the lateral geniculate nucleus (LGN) of the thalamus to the primary visual cortex (V1) and extrastriate visual areas, V2 and V4, and culminating in the inferotemporal (IT) cortex. In turn, IT provides a major source of input to the prefrontal cortex (PFC), which is involved in linking perception to memory and action (see DiCarlo et al. 2012, for review). A single feedforward pass through the visual cortex rapidly produces a coarse image representation sufficient for rapid object classification. Evolutionarily, such rapid feedforward processing might have been enabled the split-second detection of predators necessary for survival (Thorpe et al. 2001).

The function of feedback/recurrent connections are less well understood. By “feedback,” we mean those connections which carry information either from a higher to a lower cortical area (top-down feedback) or within a cortical area (lateral or horizontal feedback). Top-down feedback is mediated by descending projections connecting, for example, V2, V4, and IT to V1 or V1 to LGN (see Pennartz et al. 2019, for a review). These descending projections generally outnumber ascending ones. It is speculated that feedback serves primarily to modulate rather than drive activity in lower areas (Gilbert and Li 2013). Accordingly, circuits with recurrent connections have been implicated in the dynamic maintenance of image representations via attention and working memory (Gazzaley and Nobre 2012) and other modulatory processes (Lamme et al. 1998;

Angelucci and Shushruth 2013; Gilbert and Sigman 2007).

The goal of hierarchical models of the visual cortex is to explain how cortical anatomy and physiology, particularly the hierarchical arrangement of visual areas, give rise to complex visual behaviors including object recognition. Such models can be broadly classified into feedforward and feedback varieties and have their origin in computational neuroscience, where biological realism is the primary concern. Recently, however, computer vision models, notably deep convolutional neural networks (CNNs), have emerged as the best predictors of neural activity (see Serre (2019) for a review), despite their being largely unconstrained by biology.

First, we will provide an overview of feedforward hierarchical models of the visual cortex. One of the primary objectives of these models is to explain rapid visual categorization (see Serre (2016) for a review). Consequently, feedforward hierarchical models must address the ability of feedforward cortical pathways to extract features which are both selective for natural object recognition and invariant to irrelevant image transformations, including pose and illumination. The balancing of these two factors is sometimes called the “invariance-selectivity” trade-off (Geman 2006). Second, we will turn to feedback models of visual processing. These network models seek to explain how an initial, coarse feedforward representation can be dynamically manipulated with executive, mnemonic, and other processes. Finally, we will briefly discuss the problem of learning in hierarchical models.

Feedforward Hierarchical Models

Feedforward hierarchical models of the visual system have a long history starting with Marko and Giebel (1970)’s homogeneous multilayered architecture and later Fukushima (1980)’s neocognitron. One of the key principles in the neocognitron and other modern hierarchical models originates from the pioneering physiological studies and models of Hubel and Wiesel (1962). In these networks, the receptive fields of units at one

level of the hierarchy are constructed by combining inputs from units at a lower level. Numerous feedforward models of the ventral stream of the visual system have been described since the neocognitron to account for the organization and the neurophysiology of the ventral stream of the visual cortex. These models can be coarsely divided into conceptual proposals (Biederman 1987; Perrett and Oram 1993; Hochstein and Ahissar 2002) and neurobiological models (e.g., Wallis 1997; Mel 1997; Riesenhuber and Poggio 1999; Ullman et al. 2002; Thorpe 2002; Amit and Mascaro 2003; Wersing and Koerner 2003; Serre et al. 2007; Masquelier and Thorpe 2007). Similar hierarchical models have also been proposed to explain motion processing in the dorsal stream of the visual cortex (e.g., Simoncelli and Heeger 1998; Grossberg et al. 1999; Perrone and Thiele 2002; Giese and Poggio 2003; Rust et al. 2006; Jhuang et al. 2007; Pack and Born 2008; Mineault et al. 2012).

Somewhat independently, convolutional neural networks (CNNs) and other deep learning architectures have been developed in computer vision (see LeCun et al. 2015, for review). CNNs typically involve two processing stages: a feature extraction stage, in which visual information is passed through layers of computing units having small receptive fields, and a classification stage, in which the resultant features are combined by “fully connected” units having global receptive fields. In the most common computer vision setting, the parameters of these models are gradually adjusted by the backpropagation algorithm to minimize classification error on a large data set of labeled images. After supervised training, the network approximates a function from the space of natural images to a set of discrete object labels. These neural networks do not mimic the organization of the visual system in detail, but biology is often cited as a source of inspiration, and they nevertheless provide a better fit to experimental data than earlier biological models (Yamins et al. 2014).

Modeling of feedforward pathways in the visual cortex begins with the description of primary visual cortex by Hubel and Wiesel (1962). Hubel and Wiesel famously described two

functional classes of cortical cells: simple cells, which respond to oriented stimuli (e.g., bars, edges, gratings) at particular orientations, and complex cells, which, while also tuned to oriented stimuli, tend to have larger receptive fields and exhibit some tolerance to the exact position of the stimulus within their receptive fields. A V1-like circuit is shown in Fig. 1, which connects a complex cell to an array of simple cells tuned to the same feature at neighboring locations.

Though such models help to explain the basic invariance properties of key neural circuits, they do not explain the careful balance of invariance and selectivity needed to solve the problem of natural object recognition. To understand the limitation of these circuits more clearly, consider the following classic example of Geman (2006) (Fig. 2). A collection of simple cells are tuned to vertical bars. One subset, S1, of these cells feeds into complex cell, C1, and an overlapping subset, S2, feeds into complex cell C2. One of the proposed functions of complex cells in the visual system is the gradual introduction of invariance, since, for example, C1 and C2 will be as active when presented with two bars in the configuration of Fig. 2a as they will when presented with the configuration of Fig. 2b. In other words, the activation patterns of C1 and C2 cannot distinguish between a broken and a continuous line. This problem generalizes: a V1-like circuit consisting of a few face features with tolerance to small translations will tend to detect faces (Geman 2006) even when it should not (Fig. 2c vs. 2d). Such a circuit appears to be insufficient to fully achieve selective and invariant object recognition.

Contemporary feedforward models of the visual cortex partially resolve this “invariance-selectivity” dilemma by introducing further, “deeper,” processing stages, each with numerous learned filters. These models are an extension of the Hubel and Wiesel’s circuit from V1 to higher areas of the ventral stream. They come in numerous forms, differing in their specific wiring and neuronal operations. However, common to most of these network models are three key ingredients: (1) a cascade of linear filters each followed by (2) a pointwise nonlinearity which introduces

Hierarchical Models of the Visual System, Fig. 1 Hubel and Wiesel model. (a) Receptive field (RF) of a simple cell (lower green cell) obtained by selectively pooling over afferent center-surround cells (upper green cells) aligned along a preferred axis of orientation (vertical shown here). (b) At the next stage, a complex cell (lower green cell) RF can be obtained by selectively pooling over afferent simple cells (upper green cells) with

the same preferred orientation (vertical). Shown here is a complex cell RF obtained by pooling over position to build tolerance to translation of the preferred stimulus, but a more complete model of a complex cell would also include pooling over simple cells tuned to slightly different spatial frequency and phases (Rust et al. 2005; Chen et al. 2007). (Modified from Hubel and Wiesel (1962))

Hierarchical Models of the Visual System, Fig. 2 The invariance-selectivity trade-off. Two complex cells C1 and C2 pool over overlapping sets of simple cells tuned to vertical bars. Being translation invariant, the cells respond identically to the broken bars in (a) as they to the continuous bar in (b). Similarly, a collection of complex cells

tuned to face parts may erroneously detect a full face (c) if facial components are subject to small translations (d). See Geman (2006) for details. Arguably, the visual system avoids these false alarms for thousands of fine-grained object categories while remaining invariant to irrelevant image nuisances, like illumination, contrast, and pose.

tolerance to noise and (3) gradual, intermittent max/average pooling for translation invariance (see Mallat 2016, for a theoretical justification of these three parts). The result is an architecture which gradually builds hierarchical compositions of visual features up to and including natural

objects. Such a feature hierarchy is depicted for the case of Hmax, a classical hierarchical model of visual processing (Riesenhuber and Poggio 1999; Serre et al. 2007), in Fig. 3.

A general wiring diagram of a feedforward model of the visual system is shown in Fig. 4.

Hierarchical Models of the Visual System, Fig. 3 Sketch of the Hmax hierarchical model of visual processing. Acronyms: V1, V2, and V4 correspond to primary, second, and fourth visual areas and PIT and AIT to posterior and anterior inferotemporal (IT) areas, respectively (tentative mapping with areas of the visual cortex shown in color, parietal cortex and dorsal stream not shown). The model relies on two types of neural operations: a max-like pooling operation (shown in dash circles) over similar features at different positions and scales to gradually build tolerance to affine transformations and a convolution (also called tuning) operation (shown in plain circle) over multiple features to increase the complexity of the underlying representation. Since it was originally developed Riesenhuber and Poggio (1999), the model was shown to explain a number of new experimental data (see Serre and Poggio 2010, for a review). However, today this model and similar architectures have been superseded by deep convolutional networks that have been shown to provide a better fit to neural data along the ventral stream of the visual cortex (Serre 2019)

A layer of simple cells is conceived as a bank of feature detectors, each selecting for one of K different features within a local neighborhood centered at spatial location, u , in the layer's input (see Ullman and Soloviev 1999, for a discussion of the biological realism of this architecture). Each simple cell computes a weighted sum of afferent unit activities,

$$y_u^{(k)} = \sum_{v \in \Omega_u} w_v^{(k)} x_v, \quad (1)$$

where k indexes the particular feature to which the simple cell is tuned, Ω_u are the locations of afferent units in the input pool, x_v are those units' activities, and w_v are the synaptic weights connecting each afferent to the simple cell target. The scalar $y_u^{(k)}$ is analogous to an average firing rate of the simple cell. Since feature detectors are replicated at each spatial location, the output of a simple cell layer can be modeled as a convolution of the afferent signal, x , with a bank of features $\{w^{(k)}\}_{k=1}^K$ of small support:

$$y^{(k)} = w^{(k)} \star x.$$

The pattern of activations $y^{(k)}$ for a given k is called a feature map (Fig. 4, red rectangle). Note that we have written the output of a layer of simple cells as a 2D convolution, though, in general, the summation can be taken across many dimensions, including time, input channels, eye dominance, etc.

The vector $(y_u^{(k)})_{k=1}^K$ for a fixed location, u , is called a hypercolumn (Fig. 4, green prism) and represents an encoding of the afferent activity with respect to the features $\{w^{(k)}\}$. In the primary visual cortex, these local descriptors are well modeled by Gabor wavelets (as shown in RF₁ in Fig. 4), tuned to different orientations and scales, and these filters often emerge in models trained on natural images, especially when activity in the network is encouraged to be sparse (Olshausen and Field 1996; Lee et al. 2008). Iteratively combining the supports of filters throughout the hierarchy which feed into a given unit yields its receptive field; e.g., in Fig. 4, the shaded region RF2 is the union of receptive fields of its afferent

Hierarchical Models of the Visual System, Fig. 4 Feedforward wiring diagram. Hierarchical

models of the visual system are characterized by multiple stages of processing whereby units in one stage (shown as squares) pool over the response of units from the previous stage. Each stage computes a convolution of the previous stage with a bank of K filters, and a unit's activity is the

output of this convolution at a given location. The convolution with a given filter is called a *feature map* (e.g., the outputs of cells in the red square). The set of feature activations at a given location is called a *hypercolumn*. The output of a layer is passed through a pointwise non-linearity and max or average pooling, after which it forms the input for another bank of filters. See text for details

units in Ω . Comparing the size of RF_1 and RF_2 , we see that iterative pooling in this manner gradually increases the size of receptive fields as one proceeds up the feature hierarchy.

The output of a simple cell layer is typically passed through a pointwise nonlinearity, ρ , called an activation function in order to provide some robustness to noise and increase the expressiveness of the visual representation:

$$\begin{aligned} \hat{y}^{(k)} &= \rho(y^{(k)}) \\ &= \rho(w^{(k)} \star x). \end{aligned} \quad (2)$$

Typical choices for ρ include rectification, logistic, or hyperbolic functions. The standard choice in computer vision for ρ is zero rectification. In this context, a scalar bias, b , on the output of a simple cell layer functions as a spiking

threshold, since $y_u = \max(0, (w * x)_u - b) > 0$ only when $(w * x)_u > b$. A model neuron which passes a linear combination of its afferents through a pointwise nonlinearity is called a linear-nonlinear (LN) neuron (Simoncelli et al. 2004). The LN model has been shown to account for a host of experimental data (Rieke et al. 1997), and it has been shown that in many cases, biophysically more realistic, spiking neuron models can be reduced to a simple LN cascade (Ostojic and Brunel 2011).

Extensions of the LN cascade include the addition of a normalization stage (Heeger 1993; Carandini and Heeger 1994), in which the response y_u of the neuron is divided by a factor that typically includes the summed activity of a pool of neurons:

$$y_u = \frac{\sum_{v \in \Omega_u} (w_v x_v)^p}{\epsilon + \left(\sum_{v' \in \Omega'_u} x_{v'}^q \right)^r}, \quad (3)$$

where $\epsilon \ll 1$ is a constant to avoid zero-division. The pool of neurons Ω'_u used for normalization may correspond to the same pool of neurons Ω_u which shape the classical receptive field or may extend beyond to account for extra-classical receptive field effects (Series et al. 2003). Normalization circuits were originally proposed to explain the contrast response of cells in the primary visual cortex and are now thought to operate throughout the visual system and in many other sensory modalities and brain regions (see Carandini and Heeger 2012, for a review).

Complex cell layers filter their input with a fixed low-pass or max filter, the latter of which is the standard in computer vision. If a max-pooling unit at location u receives input from a pool of afferent units Ω_u , then the unit outputs

$$y_u = \max_{v \in \Omega_u} \{x_v\}, \quad (4)$$

where x is itself usually the activity of a simple cell layer. Interestingly, maximum, Gaussian, sigmoid, and other types of cell tuning can all be

approximated by various forms of Eq. 3 depending on the values of the static nonlinearities p , q , and r in the underlying neural circuit. By adjusting these nonlinearities, Eq. 3 can approximate better a maximum or other tuning functions (see Kouh and Poggio 2008, for details).

While recent work has suggested that simple and complex cells may represent the two ends of a continuum instead of two discrete classes of neurons (see Ringach (2004) for a discussion), this dichotomy is probably not critical for hierarchical models of the visual system. Indeed, some computational models do not distinguish between simple and complex cell pooling (O'Reilly et al. 2013).

Deep convolutional neural networks with an architecture similar to that of Fig. 4 have achieved impressive results in image classification, by some measures surpassing human performance (He et al. 2015). Many of the most powerful contemporary networks are “ultra-deep,” extending the linear-nonlinear cascade to hundreds or even thousands of layers (He et al. 2016). Often, these models are only superficially deep, as they employ “skip” connections to bypass several layers, similar to the ascending projections from V2 to IT or V1 to V4 (Nakamura et al. 1993). During training, these “residual networks” (He et al. 2015) essentially learn to adjust their processing depth to best suit a given task. For example, imagine that pairs of linear-nonlinear stages are grouped into blocks indexed by t , so that the output of the t th block is given by the nonlinear operator A_t :

$$A_t x = \rho(w_{t,2} \star \rho(w_{t,1} \star x)), \quad (5)$$

where $w_{t,1}$ and $w_{t,2}$ are two kernels of synaptic weights interleaved by pointwise nonlinearities. Skip connections add the input to this operator to the output: $A_t x + x$. Suppose that the true function to be learned by this block is $F(x)$. In an ultra-deep system, the optimal function for this block may very well be the identity map, $F(x) = x$. Bypass connections in residual nets (Fig. 5a) accelerate the learning of these identity maps since they allow the training algorithm to alternatively learn zero “residual” functions

Hierarchical Models of the Visual System, Fig. 5 Residual and recurrent circuits. (a) A residual net contains skip connections that allow a copy of activity x to bypass the t th block of layers, here encoded in the operator A_t . The copied activity, x , is then added to the output of the bypassed layers, $A_t x$, in the hopes that the model will more easily learn that the A_t operator is often the

zero operator. (b) A recurrent circuit runs in time and updates its persistent state by integrating incoming information: $y_t = A_t y_{t-1} + x_t$. (c) A residual net can be reformulated as a particular recurrent network (Liao and Poggio 2016), where the t th residual block is the state of the recurrent circuit at time t .

$$F(x) - x = A_t x. \quad (6)$$

After training, many of the A_t will have converged to the zero operator, allowing data to essentially skip a layer as the network performs a feedforward pass.

Despite being unconstrained by neurophysiology, currently the best feedforward models of visual cortical activity are deep convolutional networks developed by the computer vision community. Early computational neuroscience work started with AlexNet (Krizhevsky et al. 2012) and ZFNet (Zeiler and Fergus 2014), which were shown to improve the fit to neural data in intermediate and higher areas of the ventral stream of the visual cortex even if they were optimized for task performance (e.g., image classification accuracy) instead of neural prediction directly (Cadieu et al. 2014; Khaligh-Razavi and Kriegeskorte 2014). A recent study (Cadena et al. 2019) has shown that intermediate layers from the VGG network of Simonyan and Zisserman (2014) provide a better fit to V1 monkey electrophysiology data compared to simpler linear-nonlinear models. Work by Hong et al. (2016) has also shown that

multiple image properties beyond object categories (e.g., object position, 3D size, and pose) remain relatively well encoded in higher processing stages in both neural and CNN representations. This provides further evidence that visual hierarchies are able to learn visual representations that are invariant to task-irrelevant transformations while maintaining information for task-relevant ones.

Further evidence for hierarchical processing in object recognition comes from studies that have shown that the depth of convolutional layers that provides the best goodness of fit with brain data increases along the ventral visual stream (Cichy et al. 2016; Devereux et al. 2018; Guclu and van Gerven 2015; Kalfas et al. 2017; Khaligh-Razavi and Kriegeskorte 2014; Yamins et al. 2014). Similar results were also reported for scene recognition (Cichy et al. 2017; Greene and Hansen 2018) and action recognition (Güçlü and Gerven 2017) with spatiotemporal CNNs trained for action recognition (Tran et al. 2015). Interestingly, the goodness of fit between brain data and fully connected layers tends to be lower than with convolutional layers (Kalfas et al. 2017), a result consistent with a behavioral study that has

compared CNNs with human behavioral decisions during a rapid categorization task (Eberhardt et al. 2016). This result also seems consistent with a recent object naming study (Devereux et al. 2018) that has shown that a network model of semantics, explicitly trained to learn a mapping from the convolutional layers of a CNN onto object semantic attributes, was better able to explain functional magnetic resonance imaging (fMRI) activation patterns in higher visual areas compared to either convolutional or fully connected layers. CNNs have also been used to synthesize patterns of fMRI activations, which were then used to reproduce classic functional brain-mapping experiments, from recovering retinotopic maps in early visual areas to replicating the known faces-versus-places BOLD contrast in higher areas (Eickenberg et al. 2017).

Recurrent Models

To date, most existing hierarchical models of visual processing – from the perspectives of both biological and machine vision – are instances of

feedforward models (Serre 2019). These models have been useful in exploring the power of fixed hierarchical organization as originally suggested by Hubel and Wiesel (1962). However, the limitations of feedforward networks, in terms of their correspondence to both cortical function and anatomy, are becoming increasingly obvious. For example, convolutional networks can be easily tricked into incorrectly detecting objects in ways that biological vision cannot, either by placing familiar objects in unfamiliar arrangements (Fig. 6a; see Rosenfeld et al. (2018)) or even by adding minute perturbations to images (Szegedy et al. 2013; Geirhos et al. 2018). Evidently, deep feedforward nets have not fully resolved the invariance-selectivity dilemma and its attendant high false alarm rate. These networks also struggle to learn simple visual reasoning tasks which are trivial for humans, notably those in which arbitrary objects must be compared (Fig. 6b; see Kim et al. 2018). This limitation suggests feedforward models of the visual system cannot easily emulate humans' ability to flexibly construct innumerable structured descriptions of the visual world (Fodor and Pylyshyn 1988; Geman

Hierarchical Models of the Visual System, Fig. 6 Limitations of feedforward models. (a) A feedforward model can be trained to high accuracy on hundreds of object classes, and yet the resulting network still misclassifies objects when placed in unfamiliar arrangements. Here, the YOLO object recognition and localization deep network (Redmon et al. 2016) mistakes a penguin for a cat because of a partially occluding guitar. (See Rosenfeld et al. (2018) for a systematic analysis of

this effect; image credit: Junkyung Kim.) (b) Kim et al. (2018) found that feedforward models could easily solve spatial reasoning problems, like determining whether two random patterns are arranged vertically or horizontally (vertical axis), but had a comparatively more difficult time solving same-different tasks such as determining whether an image contains two identical, but arbitrary, patterns (horizontal axis)

et al. 2015). Naturally, feedforward models do not help explain the copious feedback and lateral connections in the visual cortex or the executive and mnemonic processes they support. Contemporary CNNs can also have hundreds of processing stages, counting skip connections, whereas the ventral stream contains a dozen or fewer. In fact, the classification accuracy of feedforward networks begins to decorrelate with human behavior after a few layers (Eberhardt et al. 2016).

Could the functional and anatomical limitations of feedforward models of the visual system be connected? Geman (2006), for instance, claims that selectivity in natural vision arises not from the learning of a large dictionary of complex visual features but rather from the dynamical construction of representations out of simple parts using recurrent connections. Recent work in recurrent neural networks (RNNs) has partially corroborated this intuition and shown that models with feedback connections are both functionally superior to feedforward networks on some tasks (Linsley et al. 2018) and better predictors of cortical activity (Nayebi et al. 2018; Kar et al. 2019).

An RNN is built from circuits with cyclical connections. For example, if x_t is a signal at time t , then such a circuit could compute

$$y_t = A_t y_{t-1} + x_t, \quad (7)$$

where A_t is a potentially nonlinear, time-dependent operator (Fig. 5b). y_t is a persistent or hidden state of the circuit which accumulates information from x_t over time. An additional operator can provide a readout or classification layer: $o_t = B_t y_t$. The principal advantage of networks built from these circuits is that the system can perform stateful computations based on the information stored in the persistent activity y_t . For example, given a memory-data combination, (y_t, x_t) , a network could learn to sequentially suppress or enhance different regions of the visual field, giving rise to exactly the kind of attentional mechanisms capable of disambiguating a cluttered scene (Treisman and Gelade 1980; Evans and Treisman 2005), as in Fig. 6a, or detecting the relations in Fig. 6b

(Donderi and Zelnick 1969; Clevenger and Hummel 2014).

Importantly, a version of the dynamical system in Eq. 7 is equivalent to the ultra-deep residual networks discussed above. If $x = x_0$, $x_t = 0$ when $t > 0$, $y_0 = 0$, and we consider the circuit in Fig. 5c with operator $A_t + I$, then we find

$$\begin{aligned} y_1 &= (A_1 + I)0 + x_0 = x \\ y_2 &= (A_2 + I)y_1 + 0 = A_2 x + x \\ y_3 &= A_3 y_2 + y_2 \\ &\vdots \end{aligned}$$

We observe that the operator A_t corresponds to the function embodied by blocks in a residual network, so that the t th block in the hierarchy is also the t th sequential operation in the recurrent circuit of Fig. 5c. In other words, an ultra-deep residual network can be “folded” into a shallow recurrent circuit (see Liao and Poggio 2016, for details). This suggests that the relatively shallow visual cortex could match the performance of ultra-deep feedforward systems by using recurrent connections through time.

Contemporary recurrent models of the visual cortex elaborate on the basic RNN structure by hierarchically stacking recurrent circuits, introducing lateral connections within a layer and top-down connections between layers, and allowing the system to gate activity. This last operation, known primarily for its use in long short-term memory (LSTM) networks (Hochreiter et al. 1997) and, later, gated recurrent units (GRUs) (Cho et al. 2014) for natural language processing, enables a network to selectively delete and append information to its persistent state. Linsley et al. (2018) recently developed a recurrent network model with lateral connectivity and gating to mimic the contour integration and object segmentation capabilities of humans in cluttered scenes (Grossberg and Mingolla 1985; Field et al. 1993; Grossberg and Raizada 2000; Grossberg and Williamson 2001). Further, Nayebi et al. (2018) and Kar et al. (2019) found that convolutional networks augmented with recurrent connections had improved performance in image classification and could predict recordings of primate IT activity

better than a feedforward baseline. These attempts to model the visual system with recurrent networks are promising, though this line of research is still in its infancy compared to feedforward modeling.

Learning

Modeling the visual system with recurrent networks is a tantalizing proposition, since RNNs are Turing-equivalent and can therefore theoretically compute any function given enough time (Hyötyniemi 1996). This is to say nothing of how this function is learned, however. Learning is the domain where differences between computational and biological models are at their starkest. In particular, CNNs are typically trained by supervision with gradient descent on millions of labeled images, whereas training in the visual system likely occurs by some combination of unsupervised and reinforcement learning. Differences with biological vision seem all the greater in light of recent evidence indicating that face preference (Reid et al. 2017), category selectivity (van den Hurk et al. 2017), and basic reasoning (Martinho and Kacelnik 2016) can require little to no visual experience to function properly.

Even the basic mechanisms of error propagation seem difficult to implement in a biologically plausible manner. Backpropagation of error has traditionally been considered biologically unrealistic since it would seem to require that feedforward connections be mirrored by identical feedback connections. Any mechanism for computing error in cortex would have to know the weights of the feedforward pathway, a dilemma known as the “weight transport” or “weight symmetry” problem (Grossberg and Mingolla 1987). However, Liao et al. (2015) found that feedforward and feedback weights need not be symmetric for successful training as long as the network was trained with batch normalization (Ioffe and Szegedy 2015) and the magnitudes of gradient updates were discarded. Further, Bengio et al. (2015) argues that spike-timing-dependent plasticity (STDP; see Sjöström and Gerstner

(2010)) is equivalent to gradient descent for a particular variational algorithm.

Though these results assuage some fears about basic error propagation in the cortical setting, they do not address the implausibility of direct supervision. A complete computational model of the visual system will have to integrate the feedforward and feedback mechanisms discussed above with methods from unsupervised learning, for example, predictive coding (Rao and Ballard 1999). See Marblestone et al. (2016) for an extensive review on the neuroscientific implementation of deep learning algorithms.

Definition

Calcium channels are one of the oldest members of the voltage-gated channel family (Anderson and Greenberg 2001) and are ubiquitous among excitable cells. Calcium channels are composed of a specialized structure, a complex protein placed to bridge the intracellular and extracellular media across the lipidic cell membrane. Under the control of the difference of potential across the cell membrane (membrane voltage or V_m) and biochemical pathways, these channels finely control the flow of calcium (Ca^{2+}) ions into excitable and non-excitable cells. The Ca^{2+} channels (Cav) are divided into different subfamilies based on their subunits types and assembly, which leads to the creation of channels with different kinetic properties and distinct function in specific sections of the cells.

Like sodium (Na^+) or potassium (K^+) channels, Ca channels show a voltage dependence of their gating variables. Their large family, 10 genetically identified types, can be roughly divided into two classes based on the range of the membrane voltage in which Ca channels open: low (LVA) and high voltage activated (HVA). HVA calcium channels contribute to neuronal excitability providing multiple functional complements to action potential generation and subthreshold integration of input. The ability of HVA calcium channels to mediate ion entry has been used by the evolution for many different purposes: from action potential generation in lower eukaryotes to fine-tuned synaptic control in higher species and from muscular contraction to hormone release and genetic expression (Anderson and Greenberg 2001).

Detailed Description

A cell is a living organism which requires an enclosed place to live, a complex system able to capture nutrients from the outer medium and to dispose of the waste produced by the cell activity. All animal cells are surrounded by a double-layered membrane able to define where, what, and when a specific substance can pass across it and in which direction. Under physiological

condition, only gases, like oxygen and CO₂, and only small uncharged polar molecules, like water or alcohol, can diffuse through the membrane. These substances are fundamental for the life of all cells and so they can diffuse freely, from the extracellular side to the cytoplasmic side and backward. In the case of ions, the lipidic membrane keeps a tight control of their flux maintaining their differential concentration across the membrane at specific levels taking advantage of complex mechanisms as internal stores, ion pumps (PMCA), or sodium-calcium exchanger (NCX). In the specific case of Ca²⁺ ions, the cellular mechanisms act to maintain a low Ca²⁺ concentration in the cellular cytoplasm and a high concentration in the extracellular matrix. The internal quantity must be kept strictly under control, as intracellular Ca²⁺ is able to activate an enormous series of local biochemical pathways, some of which are able to activate enzymes used during synaptic plasticity or to regulate other ions channels. Some others are connected with gene expression or initiate the apoptosis process leading to cell death.

Role of HVA Ca in Neuronal Dynamics

Calcium channels play a large number of key roles in neurodynamics. They can shape regenerative action potentials, provide exclusive contribution to the generation of action potentials like in cardiac pacemaker cells, and finely control the release of a single vesicle from a presynaptic terminal. In general, Ca²⁺ channels are involved in contraction, secretion, and gating. In many cell types, N/P-type HVA Ca channels contribute to the generation of after-hyperpolarization currents by increasing intracellular Ca concentration and activating K⁺ channels. In motoneurons, N/P-type Ca HVA channels contribute to the generation of after-hyperpolarization currents (Venugopal et al. 2012). In the same neurons, L- and N-channel types also couple with Ca-dependent potassium currents to increase the gain and the rate of spike frequency (Umemiya and Berger 1994). L-type calcium channels control the spontaneous activity in neurons as P/Q-type channels do in Purkinje

cells (Womack et al. 2004). In unipolar brush cells, the L-type channels help in intensifying the response induced by synaptic activity (Diana et al. 2007).

History of Names

The subfamily of HVA Cav is composed of four types: L type, P/Q type, N type, and R type. These names were given to define one specific characteristic of each channel. The L type (Cav1.1-4) is called “long lasting” because the channel remains open for a long time. This channel can be found in neurons, muscles and, above all, in the cardiac action potential generation where they play the important role of sustaining it. The P type (Cav2.1) has been called in this way by the researcher who finds it, for the first time, in cerebellar Purkinje cell (Llinas et al. 1989). This channel takes over 2 s to enter the inactivated state and this can be seen as a way, for PC, to integrate the synaptic activity over a very long timeframe. The original definition for the N type (Cav2.2) was “non-L-type” calcium channel, but now it is defined as “neuronal type” and is localized primarily in the presynaptic side of CNS synapses. The R type (Cav2.3) is called “residual” because, after blocking any other type of calcium channel with any possible toxin/drug, this channel type is still able to allow a residual calcium current (Wilson et al. 2000). For a full summary of exact names of the channel family and subunits consult the database published by Sharman et al. 2013.

Channel Subunits

A voltage-gated ion channel is composed of four proteins (called subunits) which, together, form a specific quaternary structure: a tetramer. The tetramers can be defined as homotetramers, if the subunits are all of the same type, or heterotetramers, if two or more are different. The HVA subfamily is composed only of heterotetramers. The most important subunit is $\alpha 1A$ ($\alpha 1A$) which is responsible for the selectivity of the ion

pore; it is able to sense membrane voltage changes and it provides a binding site for drugs and toxins. The auxiliary $\alpha 2$ ($\alpha 2$) and the delta (δ) subunits are very important, in the channel setup. $\alpha 2$ is able to cluster with $\alpha 1$, enhancing the channel conductance, the balance between activation and inactivation time constants, and the shift of the inactivation curve toward hyperpolarized voltages. $\alpha 2$ is coexpressed with a delta subunit (δ) that anchors the channel to the cell membrane. To give specific kinetic characteristic and to complete the tetramer, the channel incorporates one out of two types of modulatory auxiliary subunits called beta (β) and gamma (γ). There are four known isoforms of β subunit which are able to modify, even more, the activation and inactivation kinetics of any HVA channel. In Purkinje cell, the presence of β subunits can change, in a very specific way, the inactivation timing (Richards et al. 2007). Instead, the presence of γ , instead of β , subunits is responsible for the reduction of activation/inactivation kinetics and enhancement of inhibitory kinetics (Arikkath and Campbell 2003). The subunits' composition can be different for each member of the Ca^{2+} subfamily. For example, L-type channels can be composed of the combination of four out of all the available subunit types ($\alpha 1A$, $\alpha 2$, δ , β , γ), forming distinct tetramers. Conversely, P-type channels are usually composed only of $\alpha 1A$, $\alpha 2$, δ , and β subunits. Only in a few cases, the γ subunit is included in the P-type tetramer. Pushing to a higher level of complexity the range of possible properties of each channel, each subunit has different splicing alternatives giving rise to a series of subunits with slightly different biophysical properties. The existence of 10 variations of $\alpha 1A$, four $\alpha 2\delta$ complexes, four auxiliary β , and eight γ subunits is known (Catterall 2000; Tedford and Zamponi 2006).

Biophysics of HVA Calcium Channels

HVA Ca channels are sensitive to membrane voltage and to the intracellular Ca^{2+} concentration. Voltage gating is responsible of conformational changes leading to channel transitions into

or from the open, closed, or inactivated state. The intracellular Ca^{2+} concentration controls transitions from closed or open states to the inactivated state (for an example, see L-type Markov model: Mahajan et al. 2008). In spite of the large dataset available on Ca^{2+} channels conformational changes, the state of the art on their computational modeling is mainly focused on using the Hodgkin and Huxley formulation. In these computational models, Ca^{2+} channels show activation and inactivation dynamics dependent on voltage changes only, discarding the dependence of inactivation on the intracellular Ca^{2+} concentration.

An example for HVA calcium currents is L-type (slow inactivating calcium currents) high-voltage-activated calcium currents of unipolar brush cells. The channel is a Hodgkin-Huxley-based model; the source of the model is from granule cell model (D'Angelo et al. 2001) where the channel kinetics was modified for UBC-specific properties (as published in Diana et al. 2007). The alpha and beta rate function equations are listed in Table 1:

$$I_{Ca} = \bar{g} \cdot s^2 \cdot u \cdot (V - E_{Ca})$$
$$\frac{ds}{dt} = \alpha_s \cdot (1 - s) - \beta_s \cdot s$$
$$\frac{du}{dt} = \alpha_u \cdot (1 - u) - \beta_u \cdot u$$

The models currently available for HVA calcium channels are listed in Table 2. Collecting sound experimental data and modelling these kind of ion channels is a difficult task due to their complexity, modulatory mechanisms, and permeability properties.

High-Voltage-Activated Calcium Channels, Table 1 HH-based model of HVA Ca (L-type) ion channels

Transition rates	$\alpha(S^{-1})$	$\beta(S^{-1})$

Modulation of Biophysical Properties

The biophysical properties of the calcium channels are subject to modulation by many intracellular pathways. Among those the calmodulin (CaM) plays a relevant role as it binds to L-, N-, P/Q-, and R-type Ca^{2+} channels. CaM-mediated effects are widespread in the calcium channel family translating the overall neuronal activity measured by intracellular Ca^{2+} accumulation into short-term changes of gating properties leading to facilitation or inactivation. Many different computational models of CaM are currently available (Pepke et al. 2010), but they are not ready for use in the main neuronal simulators (neuron, genesis, etc.). Unfortunately, a computational model of the interaction of CaM with one of the HVA Ca^{2+} channels is not currently available.

Calcium Channel Permeability

Current-voltage relationship for voltage-gated ions is always nonlinear. The voltage dependence of ionic channels emerges from three components: the driving force acting on each ion, the ionic channel permeability, and the probability that a channel is in its open state. The Ca^{2+} current follows the concentration gradient of $[\text{Ca}^{2+}]$, in physiological conditions 10^4 – 10^5 times lower inside the cell than outside, resulting in an inward current (Tsien et al. 1988).

The thermodynamic reversal potential of Ca^{2+} is +128 mV (according to Nernst equation; Hille

High-Voltage-Activated Calcium Channels, Fig. 1 IV curve of Ca under experimental observation of chromaffin cell. (Adapted from Hille 2001)

2001), but the observed experimental value is around +54 mV (Fig. 1) (according to Goldman-Hodgkin-Katz (GHK) equation; Hille 2001). This discrepancy is explained by considering that this channels are permeable to Ca^{2+} ions and slightly permeable to K^{+} ions ($\text{P}_{\text{K}}/\text{P}_{\text{Ca}} = 1/1,000$). Although K^{+} ions permeability is low, the high concentration of K^{+} ions yields a significant contribution to the reversal potential of the HVA Ca currents. When the membrane potential goes more in positive than 0 mV, the resulting reversal potential of the HVA Ca current is dominated by K^{+} rather than by Ca^{2+} ions (Hille 2001; Tsien et al. 1987).

This counterintuitive behavior emerges from the fact that in the cytoplasm, K^{+} ions are 10^6 times more concentrated than Ca^{2+} ions. Therefore, the far lower permeability Ca^{2+} channels to K^{+} than Ca^{2+} ions must counteract an extremely large number of K^{+} ions trying to access the channel. The dotted line in Fig. 2 shows the predicted K^{+} current in flowing through Ca^{2+} channels in the case of a low K^{+} permeability, i.e., 1/1000 of the Ca permeability (assuming that the GHK equation applies). The total current carried by K^{+} and Ca^{2+} ions in this hypothetical example

High-Voltage-Activated Calcium Channels,

Fig. 2 Example: individual K^+ ions (*dotted line*) and Ca^{2+} ions (*dash line*) permeable through calcium channel. Net current passes through Ca channel (*solid line*). (Adapted from Hille 2001)

H

is drawn as a solid line. This would be the experimentally observable net current. The IV curve is less curved than for Ca^{2+} current alone and the reversal potential (+52 mV) is no longer equal to its thermodynamic value. As is probably the case for all real channels, the reversal potential here includes a weighted contribution from several ions (Hille 2001; Tsien et al. 1987).

Definition

Computational models of muscles serve as important tools to understand the musculoskeletal physiology and biomechanics. Such models have been widely implemented in a variety of simulation platforms and incorporate varying degrees of physiological details. This entry summarizes a simplified two-component biomechanical muscle model, first described by A. V. Hill in 1938, popularly known as the *Hill's muscle model*. The Hill's model provides thermodynamically constrained quantitative relationships between

muscle length, shortening velocity, force, and heat released during a muscle contraction. The model description, simulations, and MATLAB script provided here highlight the computational features of the Hill's muscle model.

Detailed Description

Biomechanical Components of Muscle Force Generation

Muscle cells contract to produce movement. During a contraction, the shortening of a muscle cell results in tension or force production. The basic structural components involved in force production consist of a *series elastic element* and a *contractile element*. The series elastic element is composed of tendons and aponeurosis. Tendons are tough extensions of the muscles, and aponeurosis is thin sheets of tissue that attach the muscle to the bone. The contractile element is composed of sarcomeres which consist of thin actin filaments and thick myosin filaments. The sarcomeres form subunits called myofibrils which are long filaments bundled into muscle fibers (see Fig. 1). The myosin heads of the thick filament form crossbridges with the adenosine triphosphate (ATP) binding sites on the thin actin filaments. To produce force in the muscle cell, the filaments slide past each other when bound to ATP. More details on muscle biology, molecular mechanisms, and dynamics of force generation can be found in (Enoka and Pearson 2013).

In his seminal paper (1938), A.V. Hill details his extensive experiments measuring the length,

velocity, force, and the energy released during muscle contractions (Hill 1938). Based on such physiological measures, Hill proposed a mathematical relationship between energy, force, and velocity of muscle shortening/lengthening (also see (Holmes 2006)). It is noted that the details of muscle biology were unknown at that time.

Model Description

A Two-Component Biomechanical Model for Force Production

A highly simplified biomechanical muscle model conceived by A.V. Hill consists of series elastic and contractile elements as shown in Fig. 2.

The series elastic element is assumed to be a spring-like structure with length, L_{se} , and the length of the contractile element is given by L_{ce} such that, the total muscle length, L , is:

$$L = L_{ce} + L_{se}$$

During an isometric contraction, the L_{ce} gradually reduces to mimic shortening of the contractile element. In parallel, the L_{se} gradually increases (muscle stretch), to account for the constant muscle length. The contraction force of L_{ce} is exactly the same as the stretching force of L_{se} . Such a force, P is assumed to be proportional to the stretch in L_{se} (Hooke's Law) as given below (also see Loiselle et al. 2008).

$$P = \alpha(L_{se} - L_{se}(0))$$

Hill's Model for Muscle Physiology and Biomechanics, Fig. 1 Structural components of a muscle. Schematic illustrating the main structural components of a muscle

Hill's Model for Muscle Physiology and Biomechanics,

Fig. 2 Biomechanical components of a muscle.

A schematic showing the biomechanical equivalence of the structural components of a muscle

where α is the spring constant and $L_{se}(0)$ is the length of the series elastic element before the contraction. The rate of change in L is therefore:

$$\frac{dL}{dt} = \frac{dL_{ce}}{dt} + \frac{dL_{se}}{dt} = v_{ce} + \frac{dL_{se}}{dt}$$

where v_{ce} is the shortening velocity of the contractile element. Similarly, the rate of change of P is given by:

$$\frac{dP}{dt} = \alpha \frac{dL_{se}}{dt}$$

From the above, it is noted that during length changes, the force P responds to length change primarily in L_{se} . For isometric contractions, in which the total muscle length is held constant, the contractile element subsequently readjusts to restore the L_{se} and therefore the force, P .

Heat Released and Force-Velocity Relationship

The original formulation for the force-velocity relationship given by A.V. Hill was based on the measurements of heat released during muscle shortening. The heat released depends on the distance (x) and velocity (v) of shortening. To measure these relationships, Hill's experiments consisted of testing the effect of different shortening velocities on the heat released during shortening. To achieve a consistent initial condition, he

began at the tetanic force, P_0 , during an isometric contraction and subsequently measured the heat released during muscle shortening for varying loads (P) (also see Figs. 4, 5, and 6). The heat released during muscle shortening is given as ax , $g.cm$, where a was experimentally determined to be a constant and has the unit of force. Next, if P of load is lifted by the muscle, the work done is given as Px , $g.cm$.

The total energy in excess of the isometric contraction is given as:

$$h = (P + a)x, \text{ in } g.cm$$

The rate of change in energy is therefore written as:

$$\frac{dh}{dt} = (P + a) \frac{dx}{dt} = (P + a)v$$

Experimentally, Hill found that this rate of change of energy release increased linearly as the load, P , diminished such that it was zero when $P = P_0$. This relationship is known as the famous Hill equation and relates the rate of heat released during muscle shortening to the corresponding load/force, as given below:

$$(P + a)v = b(P - P_0)$$

where b is the slope of the above linear relationship. The constant b is defined as the absolute rate of energy liberation.

Hill's Model for Muscle Physiology and Biomechanics, Fig. 3

A flow chart of the computational steps of Hill model. The model input is the assumed muscle length (L), and outputs include lengths of the series elastic and contractile elements, velocity, force, and heat released. The ovals indicate computational steps

Hill's Model for Muscle Physiology and Biomechanics, Fig. 4

Force-Length Relationship. In the above simulation, L_{se} was set to 30 % of the total muscle length, L . The simulation included motor noise in order to more realistically model physiological force production

Model Simulations

Figure 3 illustrates a flow diagram of the computational steps of the two-component biomechanical muscle model. The changes in muscle length (L) are translated into force (P) and heat production (H). The model reproduces known physiological relationships between these quantities. The description here is restricted to isometric conditions where the muscle length is

held constant to generate a corresponding steady-state force.

Force-Length Relationship

Figure 4 illustrates the force generation during an isometric contraction. In this simulation experiment, the initial length L_{se} is set 30% of the total length L at rest, such that the L_{ce} is at 70% of L ; note that the force is zero. To mimic

Hill's Model for Muscle Physiology and Biomechanics,
Fig. 5 Relationship between force and shortening velocity. Red circles show the steady-state force for different values for shortening velocity in individual simulations. The blue line shows a regression fit highlighting an inverse force-velocity relationship

muscle shortening during an isometric contraction, the value of L_{ce} is reduced to 60% of L . Note that this change in length is not instantaneous but has an initial transitory phase as L_{ce} shortens and L_{se} increases to ensure L is constant. Correspondingly, the force, P , increases. After stabilization of L_{ce} and L_{se} , the force P saturates at the steady-state value of the isometric contraction. A white noise was added to the force function in these simulations to match realistic conditions.

Force-Velocity Relationship

Hill empirically demonstrated that when held at the tetanic condition during an isometric contraction, subsequent increases in muscle load, P , decreased the shortening velocity, v , of the muscle over a distance, x , cm. Such experiments can be simulated in the model to reproduce this force-velocity relationship. As shown in Fig. 5, beginning at an isometric force of 150 mN, the shortening velocity, v mm/s, was changed from a value 0 to 1 in repeated simulations to compute the resulting steady-state

force. This inverse force-velocity relationship is summarized by an exponential regression fit as shown in the figure.

Length-Heat Relationship

Hill demonstrated that the heat released during muscle shortening is independent of the shortening velocity. This critical aspect on the thermodynamics of isometric contraction is illustrated by the simulations in Fig. 6. The muscle model was released from an isometric tetanus at 2 s and was subject to different shortening velocities as shown in Fig. 6a. The corresponding heat liberated as shown in Fig. 6b depends only on the shortening distance x (here, $x = 0.5$ mm) and not on the shortening velocity. Specifically the total amount of heat released due to muscle shortening was the same across all of the simulations, despite varying shortening velocities. These results demonstrate that the shortening distance x is a crucial determinant of the energy released by the muscle. When held in completely isometric conditions, the energy released is zero because there is no change in distance.

H

Hill's Model for Muscle Physiology and Biomechanics, Fig. 6 Force-Velocity and Length-Heat Relationships. (a). The muscle was held in isometric tetanus for 2 s, after which it was subject to different shortening velocities. From right to left, the shortening velocities shown are 1 mm/s, 0.50 mm/s, 0.33 mm/s, 0.25 mm/s, 0.20 mm/s, and 0.17 mm/s. After undergoing a period of shortening, all of the simulations ended at the same final length, which

was $\frac{1}{2}$ of the original length of the muscle at isometric tetanus. (b) The heat released by the muscle for the different shortening velocities in (a) is plotted (heat responses are color matched with traces in a). Over shorter periods of shortening, the rate of energy released is higher or reaches the maximal level more quickly; for this simulation, the end length was the same and notes that the energy released at the end of shortening is the same across all trials

Conclusion

Computational models of muscles help explain the principles of muscle physiology and force generation. The Hill model described here offers insights into the

relationships between muscle length, force, velocity, and heat released based on the classic experiments by A. V. Hill (1938). The model is useful to begin understanding the quantitative aspects of muscle physiology and biomechanics.

Definition

Hippocampal memory prosthesis is a brain-machine interface device developed for restoring or enhancing memory functions (Berger et al. 2010, 2011, 2012; Hampson et al. 2012, 2013; Song et al. 2006). It is designed to circumvent damaged hippocampal regions by re-establishing the transformation of spike trains performed by a normal population of hippocampal neurons. The objective is to restore long-term memory function in a stimulus-specific manner using a multi-input, multi-output (MIMO) nonlinear dynamical model (Fig. 1).

Detailed Description

The hippocampus is responsible for the formation of new long-term episodic memories (Milner 1970; Squire and Zola-Morgan 1991; Eichenbaum 1999). It receives signals carrying short-term memories from neocortices and transforms them with its feedforward pathways into signals that can be stored as long-term memories back in neocortices. Degeneration and malformation of hippocampal neurons are the underlying

Hippocampal Memory Prosthesis, Fig. 1 A conceptual illustration of the hippocampal memory prosthesis for restoring memory functions. The hippocampal memory prosthesis bypasses a damaged region by reinstating output spike trains from input spike trains using a biomimetic multi-input, multi-output (MIMO) model

cause of the memory disorders associated with stroke, epilepsy, dementia, and Alzheimer's disease.

The hippocampal memory prosthesis is a biomimetic system that consists of three components: (1) a multielectrode array for recording the ensemble spike trains from an upstream hippocampal region, e.g., CA3, (2) a computational unit with a MIMO nonlinear dynamical model for predicting the output (e.g., CA1) ensemble spike trains based on the ongoing input (e.g., CA3) ensemble spike trains, and (3) an electrical stimulator for stimulating the downstream hippocampal region, e.g., CA1, with the predicted output spatiotemporal patterns of spikes.

The MIMO nonlinear dynamical model of input-output spike train transformation takes the form of the sparse generalized Laguerre-Volterra model (Song and Berger 2010; Song et al. 2009a, b, 2013, 2018; Fig. 2). A MIMO model is a concatenation of a series of multi-input, single-output (MISO) models that each can be considered a physiologically plausible spiking neuron model (Song et al. 2006, 2009a). Each MISO model consists of (a) a MISO Volterra kernel model transforming the input spike trains (x) to the synaptic potential u , (b) a Gaussian noise term capturing the stochastic properties of spike generation, (c) a threshold for generating output spikes, (e) an adder generating the pre-threshold membrane potential w , and (d) a single-input, single-output Volterra kernel model describing the output spike-triggered feedback nonlinear dynamics. The second-order self-kernel model can be mathematically expressed as:

$$w = u(k, x) + a(h, y) + \varepsilon(\sigma)$$

$$y = \begin{cases} 0 & \text{when } w < \theta \\ 1 & \text{when } w \geq \theta \end{cases}$$

$$u(t) = k_0 + \sum_{n=1}^N \sum_{\tau=0}^{M_k} k_1^{(n)}(\tau) x_n(t - \tau) + \sum_{n=1}^N \sum_{\tau_1=0}^{M_k} \sum_{\tau_2=0}^{M_k} k_{2s}^{(n)}(\tau_1, \tau_2) x_n(t - \tau_1) x_n(t - \tau_2)$$

$$a(t) = \sum_{\tau=1}^{M_h} h(\tau) y(t - \tau)$$

The zero-order kernel, k_0 , is the value of u when the input is absent. First-order kernels $k_1^{(n)}$ describe the linear relation between the n th input x_n and u , as functions of the time intervals (τ) between the present time and the past time. Second-order self-kernels $k_{2s}^{(n)}$ describe the second-order nonlinear relation between pairs of spikes in the n th input x_n as they affect u . N is the number of inputs. h is the linear feedback kernel. M_k and M_h denote the memory lengths of the feedforward process and feedback process, respectively. Additional model terms such as the second-order cross-kernels and third-order kernels can also be included.

To facilitate model estimation and avoid overfitting, the Volterra kernels are expanded with basis functions b such as Laguerre basis or B-spline basis (Song et al. 2006, 2009a, b):

$$u(t) = c_0 + \sum_{n=1}^N \sum_{j=1}^J c_1^{(n)}(j) v_j^{(n)}(t) + \sum_{n=1}^N \sum_{j_1=1}^J \sum_{j_2=1}^J c_{2s}^{(n)}(j_1, j_2) v_{j_1}^{(n)}(t) v_{j_2}^{(n)}(t) \\ a(t) = \sum_{j=1}^L c_h(j) v_j^{(h)}(t)$$

where $v_j^{(n)}(t) = \sum_{\tau=0}^{M_k} b_j(\tau) x_n(t - \tau)$, $v_j^{(h)}(t) = \sum_{\tau=1}^{M_h} b_j(\tau) y(t - \tau)$, $c_1^{(n)}$, $c_{2s}^{(n)}$, and c_h are the sought expansion coefficients of $k_1^{(n)}$, $k_{2s}^{(n)}$, and h , respectively (c_0 is equal to k_0). J is the number of basis functions.

To achieve model sparsity, the coefficients are estimated with a composite likelihood estimation method, e.g., group LASSO (Song et al. 2013, 2018). In maximum likelihood estimation (MLE), model coefficients are estimated by minimizing the negative log likelihood function

Hippocampal Memory Prosthesis, Fig. 2 Multi-input, multi-output (MIMO) model for hippocampal CA3-CA1 population dynamics. **(a)** schematic diagram of spike train propagation from hippocampal CA3 region to hippocampal CA1 region. **(b)** MIMO model as a series of multi-input, single-output (MISO) models. **(c)** structure of a MISO model

H

$-l(c)$. In group LASSO, the composite penalized criterion is written as

$$\begin{aligned}
 S(c) &= -l(c) + \lambda \left(\sum_{n=1}^N \|c_1^{(n)}(j)\|_2^1 + \sum_{n=1}^N \|c_{2s}^{(n)}(j_1, j_2)\|_2^1 \right) \\
 &= -l(c) + \lambda \left(\sum_{n=1}^N \left(\sum_{j=1}^J c_1^{(n)}(j)^2 \right)^{\frac{1}{2}} \right. \\
 &\quad \left. + \sum_{n=1}^N \left(\sum_{j_1=1}^J \sum_{j_2=1}^{j_1} c^{(n)}(j_1, j_2)^2 \right)^{\frac{1}{2}} \right)
 \end{aligned}$$

where $\lambda \geq 0$ is a tuning parameter that controls the relative importance of the likelihood and the penalty term. When λ takes on a larger value, the estimation yields sparser coefficients. λ can be optimized with a multifold cross-validation method. The MIMO model is validated with the Kolmogorov-Smirnov test based on the time-rescaling theorem.

The hippocampal memory prosthesis has been tested in rodents and nonhuman primates performing memory-dependent behavioral tasks

such as the delayed nonmatch-to-sample (DNMS) task and the delayed match-to-sample (DMS) task (Berger et al. 2011, 2012; Hampson et al. 2012, 2013). Recently, its application was successfully demonstrated in human epilepsy patients (Song et al. 2018; Hampson et al. 2018). Results showed that MIMO model-derived electrical stimulation delivered to the hippocampal CA1 region during the sample phase of DMS trials facilitated short-term memory by 37% during the task. Longer term memory retention was also tested with a delayed recognition (DR) task. Across multiple subjects, the stimulated trials exhibited significant improvement (35%) in both short-term and long-term retention of visual information.

Applications

Damage to the hippocampus and surrounding regions of the medial temporal lobe can result in a permanent loss of the ability to form new long-term memories. Because the hippocampus is involved in the creation but not the storage of new memories (Milner 1970), long-term memories formed before the damage often remain intact, as does short-term memory. The anterograde amnesia so characteristic of hippocampal system damage can result from stroke or epilepsy and is one of the defining features of dementia and Alzheimer's disease. There is no known treatment for these debilitating cognitive deficits. Damage-induced impairments in temporal lobe function can result from both primary or invasive wounds to the brain, and from secondary or indirect damage, such as in traumatic brain injury. Temporal-lobe damage-related memory loss is particularly acute for military personnel in war zones, where over 50% of injuries sustained in combat are the result of explosive munitions, and 50–60% of those surviving blasts sustain significant brain injury, most often to the temporal and prefrontal lobes. Rehabilitation can rescue some of these lost faculties, but for moderate to severe damage, there are often substantial long-lasting cognitive disorders. Damage-induced loss of fundamental memory and organizational thought processes severely

limit patients' overall functional capacity and degree of independence, and impose a low ceiling on the quality of life. Given the severity of the consequences of hippocampus and/or temporal lobe damage-induced cognitive impairments, and the relative intransigence of these deficits to current treatments, the hippocampal memory prosthesis provides a solution to the problem of severe memory deficits with its MIMO model-driven, bi-directionally communicates with the functioning brain.

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse)

Marije ter Wal and Paul Tiesinga
Neuroinformatics, Donders Institute, Radboud University, Nijmegen, The Netherlands

Definition

Oscillations result from synchronization of the underlying neural network. When a neuron fires action potentials at regular intervals, this leads to a periodic change in the membrane potential of its target cells. This periodic change only

shows up in the local field potential (LFP) or electroencephalographic (EEG) signal on the scalp if a sufficient number of neurons fire at roughly the same time, i.e., when they are synchronized.

What causes neurons to synchronize their spiking activity? This question has been extensively studied for gamma oscillations (30–90 Hz) in the hippocampus, mostly *in vitro* (i.e., in slices containing the hippocampus). Gamma oscillations were found to be induced in hippocampal slices under three different sets of conditions, leading to the identification of three gamma-generating mechanisms. Two mechanisms were named after the cell types involved in generating the oscillations: Interneuron Network Gamma, or ING, and Pyramidal Interneuron Network Gamma, or PING. The third mechanism, referred to as sparse and persistent gamma (PG), was named after its key characteristics, which distinguish it from both ING and PING.

Interneuron Network Gamma arises due to recurrent inhibitory coupling and is independent of principal cell firing. Synchrony can be achieved when the interneurons are driven to spike, inhibiting the group of neurons they project to. The targeted neurons recover from this inhibition at roughly the same time scale, delaying their spikes and hence increasing the likelihood of synchronized spiking after inhibition has decayed sufficiently.

Interneuron firing is also required in the PING mechanism, but there the interneurons are recruited by synchronized pyramidal cell spiking. Hence, the interneuron volley is always preceded by a pyramidal cell volley. PING is associated with high pyramidal cell firing rates.

While ING and PING are thought to be transient phenomena, induced by strong depolarizing inputs, sparse gamma is a long-lasting rhythm. Like ING, it does not require a high pyramidal cell firing rate; however, it is affected by modulation of excitatory synapses. Sparse gamma is therefore thought to depend on both pyramidal cell and interneuron activity, but is mediated by different connections than the PING and ING mechanisms.

Detailed Description

Hippocampal Oscillations: An Introduction

When an electrode is placed in between or close to a group of neurons, a time-varying local field potential signal (LFP) is recorded (Buzsáki et al. 2012). The LFP recorded *in vivo* typically shows periods of high and low amplitude following each other in a regular pattern. This pattern is known as an oscillation. Oscillations can be measured throughout the brain. When the power spectral density of the signal is computed and plotted, it becomes apparent that oscillations can have diverse characteristics. First, the brain's activity spans a range of frequencies, from a fraction of a Hertz up to 200 Hz (Buzsáki and Draguhn 2004). Second, power can differ between frequency bands and change over time. Oscillations have been linked to numerous brain functions, sparking great interest in the neurosciences in the past decades (Buzsáki and Draguhn 2004). Hippocampal oscillations have received a lion's share of the attention. Two frequency bands are particularly prominent and easy to distinguish in hippocampal activity: the theta band (4–10 Hz) and the gamma band (30–80 Hz, Buzsáki and Draguhn 2004). A link was discovered early on between these frequency bands and spatial navigation memory, making the study of these rhythms highly relevant (Buzsáki and Moser 2013).

Oscillations have been studied extensively in hippocampal slices of rodent brains (*in vitro*), mostly in rat. Several stimulation protocols were found to produce gamma oscillations in these slices (Whittington et al. 2011), which will be described in the next section. It allowed for the identification and description of three gamma-generating mechanisms. These mechanisms have since been studied using computer models (*in silico*) and in awake, behaving animals (*in vivo*). The mechanism behind the generation of theta oscillations is still debated, despite its putative role in spatial navigation and extensive studies into phase coding. Several models have been identified that can produce theta rhythms, but their relevance to hippocampal oscillations is unclear (see Kopell et al. 2010 and elsewhere in this encyclopedia). Here, we focus on generation of gamma oscillations, as the underlying

mechanisms are more delineated. We review the results from *in vitro*, *in vivo*, and *in silico* experiments and give a state-of-the-art description of the three gamma-generating mechanisms as well as their differences and similarities. We will also touch on the functional relevance of these mechanisms.

Three Types of Gamma Oscillations in *In Vitro* Measurements

In hippocampal slices, generation and modulation of gamma rhythms has been systematically studied by applying electrical stimulation and pharmacological manipulations. Tetanic electrical stimulation, in which a series of short pulses is applied via an electrode in the slice, induces short-lived gamma rhythms (Gloveli et al. 2010). Pharmacological manipulation is achieved by applying agonists or antagonist of membrane receptors in the bath solution in which the slice is kept. Activation of several membrane receptors, such as metabotropic glutamate receptors (mGluR), muscarinic acetylcholine receptors (mAChR), and kainate receptors (KAR, an ionotropic glutamate receptor), was shown to lead to gamma oscillations in hippocampal slices, as can an increase in bath concentration of potassium, which depolarizes the cells. Oscillations could be evoked in both the first and third cornu ammonis region (CA1 and CA3) in hippocampus, as well as in other parts of the hippocampal formation, such as dentate gyrus and entorhinal cortex (Gloveli et al. 2010).

To shed light on the mechanism behind the evoked oscillations, the role of inhibitory interneurons and principal cells was studied by selective blocking of synaptic transmission. To block excitatory synaptic transmission, the AMPA receptor antagonist NBQX was applied, while inhibitory synapses were blocked with the GABA_A receptor antagonist bicuculline. Gamma oscillations were absent when GABA transmission was blocked, independent of the area or stimulation protocol that was used (Whittington et al. 1995; Fisahn et al. 1998; Bartos et al. 2007). This finding indicates a critical role for inhibitory interneurons in the generation of gamma oscillations in

hippocampus. The oscillation frequency and power was affected when the strength and duration of GABA signalling was increased by adding benzodiazepines or barbiturates, which allosterically activate the GABA_A receptor (Bartos et al. 2007).

Surprisingly, when blocking AMPA transmission, mGluR-induced gamma oscillations in CA1 and CA3 remained (Whittington et al. 1995), but under these conditions mAChR-induced oscillations in CA3 and tetanically induced oscillations were abolished (Fisahn et al. 1998). Potassium-induced oscillations in both CA1 and CA3 were reduced, but not completely blocked.

By adding AMPA antagonists (Bartos et al. 2007). The results indicate that there are different types of dependence of the evoked gamma oscillations on principal cell (PC) activity. Hence, there are multiple gamma-generating mechanisms in these slices.

As the described data were all collected in the CA3 region of hippocampus, the results cannot be explained by differences in the anatomy of the underlying network. Instead, the stimulus protocols are expected to differ in the type of sub-network or the cell types they recruit and/or in the extent to which those are recruited during stimulation. For instance, while mGluRs and KARs are mostly found on interneurons, activation of AChRs by application of carbachol is known to activate pyramidal cells. In the mAChR activation protocol, interneurons are therefore entirely dependent on AMPA-mediated transmission for their activation, explaining the lack of oscillatory activity in the presence of AMPA receptor antagonists as a lack of interneuron recruitment.

Apart from their dependence on AMPA synaptic transmission, the rhythms obtained with different stimulation protocols differed in other characteristics as well, for instance:

- PC firing rate: pyramidal cells were found to fire either at gamma frequency or at only a few Hertz.
- Duration: electrical stimulation and potassium application produce gamma oscillations which last for seconds or minutes, while, for instance, mAChR-induced gamma can last for hours.

- Dependence on gap junctions: mAChR-induced oscillations in CA3 and potassium-induced oscillations in CA1, among others, have been shown to be dependent, to some extent, on the presence of gap junctions (pores that electrically couple adjacent neurons).
- Frequency range: different frequency bands have been found to coexist in CA1 recordings (Buzsáki and Wang 2012). Furthermore, the frequency versus stimulation amplitude curve of differently induced rhythms has different shapes, peaking at different frequencies within the gamma band (Whittington et al. 2011).

Based on these characteristics and subsequent modelling studies, the rhythms found *in vitro* have been collapsed into three groups (Whittington et al. 2011):

- Interneuron Network Gamma (ING): transient rhythms that are produced by direct stimulation of interneurons.
- Pyramidal Interneuron Network Gamma (PING): transient rhythms that are produced by stimulation of the pyramidal cells. PING is associated with high PC firing.
- Sparse or persistent gamma (PG): it requires PC firing, but at low firing rates. As the name suggests, persistent gamma is long lasting.

In the next three sections, the characteristics of each of the gamma-generating mechanisms are discussed in detail. Computer models of the three mechanisms are used to study what underlies their differences and similarities. It is important to keep in mind that these rhythms are not mutually exclusive. Instead, *in vivo* activity is likely to be composed of a mixture of the three, with the current state depending on what input was received and perhaps the computations that need to be performed.

Cell Types Involved in the Gamma Rhythm

As was shown in the preceding section, generation of gamma oscillations was disrupted when

GABA-mediated synaptic transmission was blocked, as well as, for some rhythms, when AMPA transmission was blocked. These findings indicate a crucial role for GABAergic interneurons in gamma generation. Though interneurons only make up a small portion of the total number of neurons in hippocampus, their diversity is much larger than that of pyramidal cells. Interneuron cell types are distinguished based on their electrophysiological, molecular, and morphological characteristics (see Klausberger and Somogyi (2008) for a review).

To identify the interneuron cell types involved in hippocampal gamma, two approaches can be considered. First, one can take a bottom-up approach and study the behavior of different interneuron types in a slice that is showing gamma oscillations by recording from individual neurons.

Several cell types were found to be active in accordance with the gamma cycle. Basket cells that express the calcium-binding protein parvalbumin (PV+ basket cells) were found to spike in synchrony with the gamma rhythm (quantified using the spike-field coherence, Gloveli et al. 2010; Buzsáki and Wang 2012). These cells were found to evoke gamma phase-locked IPSPs in the soma of connected pyramidal cells (Buzsáki and Wang 2012). The involvement of basket cells in gamma generation is supported by the properties of this cell type: basket cells are abundant (approx. 20% of the interneurons, Bartos et al. 2007), are densely connected to both each other and pyramidal cells (Bartos et al. 2007; Mann and Paulsen 2007), have been found to resonate at gamma frequency and spike at these high frequencies without adaptation (Bartos et al. 2007; Buzsáki and Wang 2012), and innervate the soma of pyramidal cells, making them perfectly suited for controlling spike timing, but not integration (which occurs in the dendrites), of the pyramidal cells (Mann and Paulsen 2007).

Other interneuron types that were found to co-activate with the gamma rhythm are, among others, bistratified and trilaminar interneurons. Bistratified cells showed a very high spike-field coherence and target the proximal dendrites of pyramidal cells (Klausberger and Somogyi

2008). The proximal dendrites have been found to resonate at gamma frequency (Whittington et al. 2011). Bistratified cells might therefore produce a very effective synchronizing signal, despite a low abundance. Trilaminar cells innervate neighboring areas in hippocampus and are therefore thought to play a role in the spatial spread of gamma oscillations (Whittington et al. 2011).

A second approach to identifying cell types involved in gamma generation is a top-down approach, which works by identifying which cell characteristics form the minimal requirements for gamma generation. This was studied using models of the different gamma-generating mechanisms. From these models it became clear that interneurons require fast kinetics to have an effective synchronizing effect and preferably innervate the soma or the dendritic elements close to the soma (Whittington et al. 2011). These requirements match the characteristics of basket cells, marking them as the key element to synchronization in the gamma frequency range.

Interneuron Network Gamma (ING)

The Interneuron Network Gamma (ING) mechanism is the simplest form of gamma generation. ING can be found in a model network comprised only of interneurons, as the rhythm's generation is independent of principal cells. When a drive is applied – that is, a current is injected at the soma – to the interneurons, the cells depolarize, causing them to spike at high rates. Subsequently, downstream neurons are inhibited and their firing is delayed. The projections from a neuron are divergent, meaning each neuron projects to a number of downstream neurons, causing the inhibitory effect of a spike to spread to a (small) part of the population (Bartos et al. 2007). When spikes of several neurons coincide, forming a volley, target neurons of all the neurons in the volley will be inhibited and recover from this inhibition at roughly the same point in time. Subsequent spiking of this group of target neurons is more likely to be synchronized than

before the volley, due to the synchronized inhibition. Synchrony will therefore spread through the population and oscillations can emerge (Tiesinga and Sejnowski 2009).

The ING mechanism has been extensively studied using computer models. An influential model, named after its developers, is the Wang-Buzsáki model (W-B model). It incorporates a network of conductance-based point model neurons that resemble PV+ basket cells (Wang and Buzsáki 1996). The model neurons are connected by model GABAergic synapses, with every neuron projecting to all other neurons in the network (all-to-all connections). When the interneurons are depolarized, the model shows robust oscillations in the lower gamma range within five or six cycles after stimulus onset (Fig. 1a). Replacing the all-to-all connectivity by a sparser, random connection matrix, also leads to synchrony, provided that there is enough convergence of inhibition to inhibit spiking in the downstream neurons (Fig. 1b).

The Wang-Buzsáki model demonstrates the ING mechanism in its purest form. From the model we can conclude that generation of gamma oscillations via the ING mechanism has only three requirements (Buzsáki and Wang 2012):

- Recurrent connections between inhibitory interneurons

- A time constant, due to transmission via GABA_A receptors, spreading the inhibition out in time
- Sufficient depolarization of the interneurons

The frequency of the emerging gamma oscillations in an ING network is determined by the time scale of inhibition and the level of depolarization of the interneurons. Neurons are ready to start a new volley when the drive to the neurons can overcome the remaining inhibition from the previous volley. Long decay time constants for the inhibitory postsynaptic currents (IPSCs) therefore lead to slower oscillations, or lower frequencies. A high drive, on the other hand, is able to balance out a much higher level of remaining inhibition and therefore shifts the next volley forward in time, increasing the oscillation frequency (Fig. 1c).

The Wang-Buzsáki model can provide great insight and is easy to study. When comparing it to the biological system, however, some discrepancies between model and experimental data need to be acknowledged. First, the time constant of the GABA_A receptors in the model was chosen to be 10 ms. Experimental data suggest that IPSCs due to basket cell – basket cell connectivity.

Have much shorter time constants, in the order of 1–2 ms (Bartos et al. 2007; Whittington et al. 2011), which is compensated by a high IPSC amplitude (Bartos et al. 2007). Decreasing the

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse), Fig. 1 The Wang-Buzsáki model. (a) The W-B model with synapses with a 10 ms IPSC decay time constant and all-to-all connectivity shows rapid synchronization. Within five to six cycles, the population reaches full synchrony, in which all neurons spike within a close proximity. (b) With heterogeneity in the drive to the neurons and a connection probability of 60%, the network still

shows synchrony, but spike times are more variable. (c) The oscillation frequency (vertical axis) of the population in the W-B model depends on two factors: the frequency increases with the (average) drive to the neurons (horizontal axis) and increases with a shorter IPSC decay time (compare 10 ms decay time constant (squares) to 5 ms decay time constant (circles)). (Circuit model as described in Wang and Buzsáki (1996))

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse), Fig. 2 The behavior of the Wang-Buzsáki model network is highly sensitive to the synapse parameters. (a) Fast, strong synapses, as suggested by experimental data, disrupt the oscillations in the Wang-Buzsáki model (compare Fig. 1b). (b) Oscillatory activity can be restored

by introducing a 2 ms synaptic delay in the model. (c) Changing the reversal potential of the GABA_A-mediated transmission from hyperpolarizing to shunting leads to increased levels of synchronization for strong synaptic connections and high oscillation frequencies. (Circuit model as described in Wang and Buzsáki (1996))

IPSC time constant and increasing the amplitude in the W-B model disrupts the oscillations (Fig. 2a). However, when synaptic delays between the synapses are introduced in the model, stable oscillations do occur, despite the fast IPSCs (Fig. 2b).

A second discrepancy between the W-B model and the hippocampal network is the resilience of the oscillatory activity to noise and heterogeneity in the network. Noise and heterogeneity in the tonic drive leads to variation in spike rate between neurons and makes periodic activity of individual neurons less reliable. In the W-B model, oscillations break down when the variance in drive to the neurons is larger than 5% of the mean drive (Bartos et al. 2007). Such small variability is not likely to be achieved *in vivo*, and from recordings during *in vitro* mGluR-induced oscillations, the variability in the drive across neurons is estimated to be 35% (Bartos et al. 2007). Two adjustments to the model have been found to make it less sensitive to variability in the drive: the addition of gap

junctions (Whittington et al. 2011) and changing the synapses from hyperpolarizing to shunting (Bartos et al. 2007). Gap junctions electrically couple neighboring neurons and allow activation to spread to adjacent cells almost instantaneously. Gap junctions therefore have a homogenizing effect: neighboring cells are more likely to spike simultaneously when they are electrically coupled, even if they receive different tonic drives. Gap junctions have been found to occur between basket cells, both with electron microscope imaging and with paired electrical recordings. Transgenic mice missing the gene for the most common gap junction pore protein, Connexin-36, still have mGluR-induced oscillations in CA3, but with a reduced power (Bartos et al. 2007).

Shunting inhibition has also been found to have a homogenizing effect, but through a slightly more complex mechanism than gap junctions. For shunting synapses, the reversal potential of the synaptic current is between the resting membrane

potential and the spike threshold, which has been indicated to be the case for GABA_A receptors (Mann and Paulsen 2007). In comparison, for hyperpolarizing synapses, the synaptic reversal potential is below the resting membrane potential, causing a cell at rest to hyperpolarize when the GABA_A receptor-mediated channels open. For shunting synapses, a cell at rest will not hyperpolarize, but depolarize, though not enough to reach spike threshold. Despite its depolarizing effect, shunting synaptic events prevent the postsynaptic cell from spiking, due to the increased conductance of the cell membrane, and hence, the term “inhibition” is appropriate. At low levels of excitation, the effect of increased conductance is small and the net effect of shunting is excitatory (Bartos et al. 2007). Therefore, the effect of shunting is drive dependent, with high drive leading to inhibition and low drive leading to excitation, hence homogenizing the activity of the neurons in the network if the synaptic connections are strong enough (Fig. 2c). The result is a highly synchronized population activity, but the resulting oscillations have a high frequency. The relevance of gap junctions and shunting in the generation of oscillations *in vivo* still remains to be determined. Furthermore, the potential involvement of other interneuron cell types as a stabilizing agent has so far not been considered in models (Mann and Paulsen 2007).

In the brain, interneurons do not form an isolated network. Instead, they are densely connected to (local) pyramidal cells. How do projections to and from pyramidal cells affect the ING mechanism? To test this, the W-B model has been extended with 400 pyramidal cells. In this model, when the interneurons are depolarized, while the pyramidal cells only receive a small drive, oscillations will occur via the ING mechanism (Fig. 3a). In agreement with experimental results, pyramidal cells have a low firing rate, while the interneurons spike at frequencies of a few tens of Hertz. When the connections from the pyramidal cells to the interneurons are broken, the oscillatory activity is not affected (Fig. 3b), but with broken interneuron-interneuron connections, the oscillation disappears (Fig. 3c). This indicates that the oscillation is only dependent on the

depolarization of the interneurons and not the input from the pyramidal cells, setting it apart from the PING and sparse mechanisms. We will now study those mechanisms in detail, before returning to the ING model and comparing the features of the three mechanisms.

Pyramidal Interneuron Network Gamma (PING)

The PING mechanism is thought to be recruited during sensory stimulation and could potentially play an important role in computation and communication in sensory processing areas (Whittington et al. 2011). A PING cycle starts when the pyramidal cells receive a strong input that drives them to spike. Some neurons will spike at roughly the same time. Pyramidal cell projections are highly convergent onto interneurons, with each interneuron receiving projections from approximately 1500 pyramidal cells (Whittington et al. 2011). The pyramidal cell activity triggers the interneurons to spike and thereby inhibits further activity in the pyramidal cells and interneurons they project to. The depolarization of the pyramidal cells can only trigger subsequent spikes when the inhibition has sufficiently decayed, delaying the spikes of the pyramidal cells and synchronizing them near the onset of the next cycle.

PING can be induced *in vitro* by applying a short period of pulsed electrical stimulation (tetanic stimulation) via an electrode in the slice (Whittington et al. 2011). This oscillation is short lived (Kopell et al. 2010) and is associated with high spike rate of both interneurons and pyramidal cells (Whittington et al. 2011). Both cell types spike approximately once per cycle, with the pyramidal cells always spiking before the interneurons, a pattern that has also been observed in *in vivo* recordings (Tiesinga and Sejnowski 2009; Buzsáki and Wang 2012).

The characteristics of the PING mechanism have been studied with a model that is similar to the two-population model described for the ING model. PING oscillations occur when the cell populations spike at a specific firing rate ratio

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse), Fig. 3 (a) ING mechanism in a two-population model, including pyramidal cells. (b) Breaking the connections between the pyramidal cells and the interneurons does not affect the oscillations. (c) Breaking the connections between the interneurons disrupt the oscillations, even if the interneuron drive is compensated for the

reduced inhibition, as shown here. Circuit model as described in Roberts et al. (2013), with a connection probability between interneurons of 40% and $I_e = 1.5 \mu\text{A}/\text{cm}^2$ and $I_i = 3 \mu\text{A}/\text{cm}^2$ for A and B, $I_i = 1 \mu\text{A}/\text{cm}^2$ for C. I_e and I_i correspond to the average depolarizing currents injected into the excitatory and inhibitory cells, respectively

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse), Fig. 4 (a) PING mechanism shown in a two-population model. As expected, the pyramidal cells produce a synchronized volley, followed by a volley of the interneurons at a short delay. (b) Breaking the connections between the pyramidal cells and the interneurons abolishes the oscillation, even if the interneurons are compensated for the reduced excitation through an additional

depolarizing current, as shown here. (c) Breaking the connections between the interneurons does not disrupt the oscillations, though spiking becomes somewhat more variable. The level of interneuron depolarization is increased to compensate for the reduced inhibition. Circuit model as described in Roberts et al. (2013), with $I_e = 2 \mu\text{A}/\text{cm}^2$ and $I_i = 1 \mu\text{A}/\text{cm}^2$ for A, $I_i = 2 \mu\text{A}/\text{cm}^2$ for B, and $I_i = 0.5 \mu\text{A}/\text{cm}^2$ for C

(Tiesinga and Sejnowski 2009), with isolated pyramidal cells spiking at or above gamma frequency (Fig. 4a). In the model, the origin of the oscillations can easily be checked by breaking the projections from the pyramidal cells to the

interneurons. Breaking the connections disrupts the oscillatory activity, indicating that the pyramidal cells are essential for its generation (Fig. 4b). Furthermore, oscillations can be found when there is no drive to the interneurons or when the

connections between the interneurons are broken (Fig. 4c), provided that the interneurons receive enough synaptic input from the pyramidal cells.

As in the *in vitro* and *in vivo* recordings, in the PING model pyramidal cells spike first, while the interneurons follow at a delay of a few milliseconds (Fig. 4a). The oscillation frequency in the population is the result of both the interneuron delay and the latency between the interneuron volley and the next pyramidal cell volley. The latency between the interneuron volley and the next pyramidal cell volley is determined by the time it takes the pyramidal cells to overcome the inhibition. It can be decreased by increasing the drive to the pyramidal cells, as shown by an increase in oscillation frequency (Fig. 5a, middle). Also, to some extent, the strength of the GABAergic synapses onto the pyramidal cells plays a role (Kopell et al. 2010), respectively slowing down and speeding up the oscillation. An increase in depolarization will cause the pyramidal cells to spike at a higher rate (Fig. 5a, top) and, in turn, drive the interneurons to increase

their spiking (Fig. 5a, top). As long as the ratio between pyramidal cell firing and interneuron firing is maintained, the populations will show synchrony and the oscillation frequency increases. For *in vitro* recordings, it was established that increasing the drive to the pyramidal cells leads to an increase in the oscillation frequency from 15 to about 60 Hz (Whittington et al. 2011).

The model also makes predictions for the effect of changing the drive to the interneurons. When the drive to the interneurons is increased, interneuron firing is increased, while pyramidal cells show less firing due to the increased inhibition. The model predicts three possible outcomes of changing the interneuron drive (Fig. 5b):

- When the ratio between pyramidal cell firing and interneuron firing becomes too low (i.e., high interneuron firing rates), synchrony is lost.
- When the ratio of pyramidal cell to interneuron firing enters the right range, synchronized oscillations emerge and the populations are

H

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse), Fig. 5 The effect of an increase in the tonic drive depends on the cell type to which it is applied. (a) Increasing the drive to the pyramidal cells increases the firing rate (top) of both the pyramidal cells (red) and the interneurons (blue) and increases the oscillation frequency (middle), while the delay between pyramidal cell volley and

interneuron volley is largely unaffected (bottom). (b) Increasing the drive to the interneurons increases their firing rate, while the pyramidal cell firing is reduced (top). The oscillation frequency is only slightly affected (middle), but the delay between the pyramidal cell and interneuron volleys is markedly reduced (bottom). (Circuit model as described in Roberts et al. (2013))

locked to the oscillations. On this “step,” the oscillation frequency does not change, but the delay between pyramidal cell volley and interneuron volley decreases (Tiesinga and Sejnowski 2010).

- For low interneuron firing, the inhibition cannot keep the pyramidal cells in check and synchrony is lost.

To conclude, the model predicts a change in the overall synchronization in the network with the interneuron drive. In experiments, under certain conditions, depolarizing the interneurons was found to enhance synchronization (Whittington et al. 2011).

Sparse or Persistent Gamma (PG)

The third mechanism for gamma generation has been named after two important characteristics of its activity pattern. PG is associated with low (sparse) pyramidal cell spiking, and it can last for hours. Its duration sets it apart from the ING and PING mechanisms, which are thought to be transient phenomena. Apart from this, the activity pattern of PG initially seems similar to that of ING: the interneurons spike at high firing rates (5–20 Hz, Traub et al. 2000), whereas pyramidal cells have low firing rates, between 0 and 4 Hz, and spike stochastically (Kopell et al. 2010; Whittington et al. 2011).

A more detailed study of PG brings to light important discrepancies between ING and PG. Surprisingly, genetically modified mice with ablated inhibitory synapses between PV+ basket cells still show strong persistent gamma rhythms. So, unlike ING, interneuron-interneuron interactions via chemical synapses are not essential for rhythmogenesis in PG (Whittington et al. 2011). Furthermore, when the membrane potential of individual interneurons is recorded during PG, large excitatory postsynaptic potentials (EPSPs) are found. This finding makes the PG mechanism inherently complex: how can rare and stochastic pyramidal cell spikes lead to strong excitatory inputs that drive the network to oscillate?

A possible origin of large EPSPs in interneurons during PG can be found in the presence of gap junctions. Gamma oscillations were found to be abolished when transmission via gap junctions was reduced through application of a general gap junction blocker (Whittington et al. 2011). Again, specifically blocking the connections between interneurons did not affect the oscillations, indicating that the gap junctions involve pyramidal cells. In agreement with this finding, recordings from pyramidal cells during PG reveal a high number of spikelets (Whittington et al. 2011): short transient depolarizations of the soma that resemble action potentials, but have a smaller amplitude. Spikelets are thought to result from action potentials in cell compartments that are electrotonically far from the soma. Therefore, it was hypothesized that there are axo-axonal gap junctions between pyramidal cells. These gap junctions could explain the strong EPSPs recorded in interneurons, while they could also give rise, via antidromic spikes, to the spikelets measured in the pyramidal cell soma.

Models with axo-axonal gap junctions between the pyramidal cells generated persistent gamma oscillations. However, nested within the gamma cycles, a very fast oscillation (VFO) is found. These VFOs have been observed under some experimental conditions (Whittington et al. 2011), but their significance is unclear. Another modelling study showed that oscillations with the characteristics of PG can also be obtained in a model without axo-axonal gap junctions. Here, a strong convergence from pyramidal cells to interneurons and a noisy external drive were sufficient to explain the strong EPSPs found in interneurons during PG (Kopell et al. 2010). A high noise level is thought to facilitate oscillatory behavior, as it can push the neurons to a subthreshold resonance regime: the noisy drive allows for spiking while keeping the average membrane potential at a relatively low level. Subthreshold resonance is found to be more pronounced at these lower membrane potentials, pushing the network toward an oscillatory state (Wang 2010). The mechanism underlying PG remains a topic of further discussion.

Comparing ING, PING, and Sparse Gamma

In the previous sections, a wide range of characteristics of ING, PING, and PG were discussed. In Table 1, the characteristics are summarized. Apart from these differences, a characteristic frequency response curve was identified *in vitro* for each of the mechanisms (Whittington et al. 2011). When the stimulation intensity increased, the three mechanisms showed distinct frequency changes. For low drive, the ING mechanism produced low oscillation frequencies, which increased to around 50 Hz and then decreased again for high stimulus powers. Unlike ING, induced PING showed a steady increase of gamma frequency with stimulus power, while PG showed no changes at all.

Given the characteristics in Table 1, it is possible, in principle, to distinguish between the three mechanisms in modelling studies: breaking the connections from pyramidal cells to interneurons should disrupt the PING and PG models, but not ING. PG and PING should be separable on the basis of the pyramidal cell firing pattern: while in PING pyramidal cells fire at high rates and are synchronized into a volley before interneuron firing, for PG the pyramidal cells spike sparsely and irregularly.

For experimental studies, the distinction between the three mechanisms is not trivial.

While the difference in pyramidal cell spike pattern between PING and PG is still a valid criterion, the distinction between ING and PG is not possible based on a spiking signature alone. Furthermore, how do we distinguish between a PING mechanism and an ING mechanism with a large but irrelevant pyramidal cell drive?

To allow for *in vivo* separation of the three mechanisms, we need to identify modulations of the network and its inputs that (1) can be performed without disrupting the functional properties and qualitative behavior of the network and (2) are feasible with the current technical possibilities. A possible approach is to apply optogenetic stimulation to specific cell types. For instance, stimulation of interneurons has a differential effect on the PING and ING mechanisms, as predicted from the models. For the ING mechanism, increasing the drive is predicted to increase the oscillation frequency, while for PING, it is expected to alter either the level of synchrony or the delay between pyramidal cells and interneurons. Selectively driving the pyramidal cells is expected to increase the oscillation frequency in the PING, but not the ING mechanism, where it will only affect the firing of the pyramidal cells. This modulation is hard to achieve pharmacologically, as it is not possible to drive the pyramidal cells without affecting the interneurons. However, when only pyramidal cells express

H

Hippocampal Oscillations, Mechanisms (PING, ING, Sparse), Table 1 Summary of ING, PING, and PG characteristics

Characteristic	ING	PING	PG
<i>Interneuron firing</i>	Near gamma freq.	Near gamma freq.	Near gamma freq.
<i>Pyramidal cell firing</i>	Low (<5 Hz)	At or above gamma freq.	Low (<5 Hz)
<i>Duration</i>	Short (seconds)	Short (seconds)	Long (hours)
<i>Blocked by GABA_A antagonist</i>	Yes	Yes	Yes
<i>Blocked by AMPA antagonist</i>	No	Yes	Yes
<i>Modulated by gap junction blocker</i>	Yes	No	Yes
<i>Large EPSPs in interneurons</i>	No	Yes	Yes
<i>Increase of stimulus power in vitro</i>	Peak around 50 Hz for intermediate stimulus amplitudes	Oscillation frequency increased with power	No noticeable changes

channelrhodopsin, it is possible to apply cell type-specific optogenetic stimulation. A similar approach would allow one to distinguish ING from PG *in vivo*, but more insight into the PG mechanism is required before solid predictions can be made. With those approaches, it would be possible to identify the input conditions that lead to the recruitment of the different mechanisms. Also, the possibility of coexistence of and interactions and transitions between the mechanisms and their activity signatures should be studied further, as these questions are relevant in understanding the function of the different mechanisms.

Gamma Rhythms and Cell Assemblies

The abundance of oscillations in the brain suggests a strong link, either causal or coincidental, to function. Several possible functional relations have been suggested for gamma oscillations. The possibility of a temporal code, in which the timing of a spike relative to the oscillatory background encodes information, was recognized early on (Buzsáki and Draguhn 2004). A more compelling possibility is the dynamic formation of neurons or local networks into functionally distinct assemblies. An assembly marks a temporary partnership between groups of neurons that extends across multiple gamma cycles and does not require direct synaptic connections. The formation of assemblies potentially improves computation and facilitates synaptic plasticity and communication (Buzsáki and Draguhn 2004).

The mechanisms underlying transient assembly formation have recently been explored in modelling studies. In both the ING (Buzsáki and Wang 2012) and the PING (Kopell et al. 2010) mechanisms of gamma generation, cell assembly formation can result from heterogeneity in the input to the cells. Heterogeneity causes the pyramidal cells in a population to spike at different phases of the gamma cycle: pyramidal cells receiving a strong input will spike early, while more weakly driven cells fire late in the gamma cycle. If the strongly driven pyramidal cells are numerous and/or synchronized enough,

they will recruit inhibition and spiking of weakly driven neurons is suppressed. This way, two or more cell assemblies are formed. As long as the activity of the neurons is able to “reset” completely within a gamma cycle or, in other words, if inhibition is the longest timescale in the system, the temporal ordering of spikes is maintained as long as the input pattern is maintained (Kopell et al. 2010).

Interactions between the gamma rhythm and oscillation with other frequencies are also considered important for assembly formation. At larger spatial scales, the interaction between the theta and gamma rhythms is thought to lead to synchronization between distant areas, for instance, across hippocampal hemispheres or between cortex and hippocampus (Buzsáki and Wang 2012). The local gamma rhythm can lock to the cycles of the more spatially extended theta rhythm, leading to a spatial spread of gamma synchronization, at least in models (Kopell et al. 2010).

Definition

Hippocampal theta, gamma, and theta/gamma network models refer to mathematical models of networks that are able to generate oscillations within the theta (4–12 Hz), gamma (25–140 Hz), and nested theta/gamma frequency ranges in the hippocampus.

The focus is on network models consisting of biophysically motivated cell models in the hippocampus that are concerned with network rhythm generation.

This entry discusses some common motives involved as well as questions that arise in constructing these network models, provides a tabular summary of existing theta/gamma network models, and gives further details of some of the network models.

Detailed Description

Coordinated neural activity may provide a temporal structure with which information can be processed and transmitted and can be reflected in

recordings of population activity, such as those of the local field potential (LFP). Indeed, links between network oscillations and behavior have been shown, particularly with respect to network rhythms of the hippocampus. Most notably, hippocampal theta (4–12 Hz) and gamma (25–140 Hz) rhythms are recorded during exploratory behavior and REM sleep and are thought to be critically involved in certain forms of cognition, such as feature binding, temporal encoding, decision making, spatial navigation, and episodic memory (Singer 1999; Traub et al. 1999; Salinas and Sejnowski 2001; Buzsáki 2002; Womelsdorf et al. 2007; Tort et al. 2008; Colgin and Moser 2010). In vivo, gamma rhythms are generally temporally nested within the slower theta rhythm and are termed theta/gamma rhythms (Fig. 1) (Bragin et al. 1995; Montgomery et al. 2008). Although experiments have provided much insight into how these oscillations may come about (Buzsáki 2002; Colgin and Moser 2010; Wang 2010; Colgin 2013) (see ► “Hippocampus, Theta, Gamma, and Cross-Frequency Coupling” for more details), a precise understanding of their

generation, in particular theta and theta/gamma, remains unclear.

Theta and theta/gamma network rhythms are generated intrinsically and endogenously in a complete rat hippocampal preparation in vitro (Goutagny et al. 2009; Jackson et al. 2011) and can be induced in in vitro hippocampal slice preparations through pharmacological manipulation (Fisahn et al. 1998; Gillies et al. 2002), thereby facilitating recordings of network rhythms. The hippocampus has a structured architecture, where cell bodies are often constrained to lie in a single layer, and dendritic trees and axonal projections compose well-defined laminae. This provides a setting in which one can target and identify particular cell types and permits simultaneous recordings of network and cellular levels to be done with relative ease. Thus, a plethora of experimental work focuses on cellular functioning in hippocampal network oscillations, providing a platform with which one can construct experimentally based models to gain insight into hippocampal rhythmogenesis. Modeling a theta, gamma, or theta/gamma network simplifies the complicated biological system due to a

Hippocampal Theta, Gamma, and Theta/Gamma Network Models, Fig. 1 Hippocampal theta and gamma oscillations in vivo (*top*) and in vitro (*bottom*). In vivo, gamma oscillations can be seen nested inside the slower theta oscillations (theta/gamma) in field recordings of the dentate gyrus during exploratory waking. In vitro, the theta and gamma oscillations shown were recorded

under pharmacological manipulation in the CA1 and CA3 areas (With kind permission from Springer Science+Business Media: *Hippocampal Microcircuits* (Cutsuridis, V., Graham, B., Cobb, S. & Vida, I., eds.), Part I, Chapter 8, 2010, pp. 247–276, T. Gloveli, N. Kopell, and T. Dugladze, “Neuronal activity patterns during hippocampal network oscillations *in vitro*,” Fig. 1a, c, d)

focus on particular rhythms, permitting theoretical and/or computational analyses to parse out fundamental mechanisms of the network. With such mechanistic insight, models help understand not only hippocampal rhythm generation but also pathological states that are associated with hippocampal rhythm changes. Further, model mechanisms could yield insights into rhythm generation in other brain regions.

Building Network Models and Complications Involved

Which Cell Types to Include?

The goal of many hippocampal network models is to gain a mechanistic understanding of the cellular contributions to intrinsically generated hippocampal network rhythms (e.g., Gloveli et al. 2005; Wulff et al. 2009). Thus, a first step in building a network model is to decide which cell types should be included. This is not a straightforward task: although excitatory cells far outnumber inhibitory (releasing γ -aminobutyric acid or GABAergic) interneurons, inhibitory cell networks with tonic depolarization have been shown to generate gamma oscillations (Whittington et al. 1995; Buzsáki and Wang 2012). Thus, explicitly including excitatory cells in network models may not always be critical to rhythm generation. In addition, a number of different inhibitory (GABAergic) interneuron types may be involved in local hippocampal oscillations (Klausberger and Somogyi 2008), and how critical each cell type is to rhythm generation is yet to be determined. These interneuron types exhibit a wide diversity of morphologies, synaptic targets, and firing properties (Freund and Buzsáki 1996; McBain and Fisahn 2001).

Fast-firing interneurons in particular have been suggested to play an essential role in hippocampal theta, gamma, and theta/gamma rhythms (Ylinen et al. 1995; Penttonen et al. 1998; Bartos et al. 2001; Freund 2003; Wulff et al. 2009; Colgin and Moser 2010; Gulyás et al. 2010; Jackson et al. 2011; Belluscio et al. 2012). These fast-firing cells are most often regarded as parvalbumin-positive (PV+) basket cells, although other fast-firing interneurons may also contribute to these rhythms

(e.g., PV+ axo-axonic and bistratified cells). Oriens-lacunosum-moleculare (O-LM) interneurons have their cell bodies constrained to the stratum oriens, but their axonal projections target the distal dendrites of pyramidal cells in the stratum lacunosum-moleculare. Maccaferri and McBain (1996) showed that they tend to fire spontaneously at theta frequencies (but see Kispersky et al. 2012) and are therefore thought to play an important role in theta oscillations. Furthermore, more models exist of O-LM and PV+ interneurons than of other interneuron types (see ► “Hippocampus, Model Inhibitory Cells”). This is true for a number of reasons, including ease of recordings and prevalence of interneurons. For example, O-LM and PV+ cells are more numerous in the CA1 region than some other interneuron types, such as cholecystikinin (CCK) and vasoactive intestinal protein (VIP) interneurons (Jinno and Kosaka 2006). Consequently, fast-firing and O-LM interneurons are the most common interneuron types to be included in theta, gamma, and theta/gamma hippocampal network models. However, it remains to be seen whether other interneuron types are critically involved in the generation of these local rhythms.

How to Model Individual Cells?

Neurons are often represented either by simple spiking models (e.g., the leaky integrate-and-fire model. See ► “Integrate and Fire Models, Deterministic” in this Encyclopedia) or by conductance-based models (Skinner 2006). The computational efficiency of simple spiking models, such as the leaky integrate-and-fire model and the Izhikevich model (Izhikevich 2003), makes them good candidates for examining network dynamics (e.g., Ferguson et al. 2013). However, to address more biophysically detailed questions, conductance-based neuron models are used (e.g., Orbán et al. 2006).

The level of detail incorporated in conductance-based neuron models varies greatly depending on the question at hand and on the availability of experimental data. Firing properties, ion channel densities and kinetics, and synaptic transmission have been studied extensively in hippocampal excitatory cells, and therefore many detailed

multi-compartment models of these cells exist (see ► [“Hippocampus, Model Excitatory Cells”](#)). Depending on the question being addressed, some network models will incorporate these highly detailed excitatory cell models (e.g., Orbán et al. 2006), while others will prioritize computational efficiency and use simpler models (e.g., Wulff et al. 2009). However, much less is known about the various interneuron types involved. This, in combination with the need for computational efficiency in large networks, commonly leads to the use of simple single-compartment conductance-based models to represent hippocampal interneurons in these network models (see ► [“Hippocampus, Model Inhibitory Cells”](#) for some examples).

How Is the Network Connected?

Additional considerations arise for modeling the connectivity of the network. For example, synaptic connections from fast-firing basket cells to O-LM interneurons have yet to be shown experimentally. Some network models assume that this connection exists (e.g., Gloveli et al. 2005; Tort et al. 2007; Wulff et al. 2009), while others assume it does not (or is not a critical connection) (e.g., Orbán et al. 2006; Neymotin et al. 2011). O-LM interneurons have been shown to synapse onto PV+ interneurons (Katona et al. 1999), but the strength of this connection, and whether this synapse plays a critical role in local rhythms, remains unclear. Therefore, some models include this connection (e.g., Gloveli et al. 2005; Orbán et al. 2006; Tort et al. 2007; Wulff et al. 2009), while others do not (e.g., Neymotin et al. 2011). Synaptic strengths and kinetics of the connections need to be considered as well. For example, Bartos et al. (2002) used a much smaller time constant for recurrent fast-spiking interneuron inhibitory postsynaptic current (IPSC) dynamics than Wang and Buzsáki (1996), which influences both coherence and frequency of the oscillations.

Further, topology or architecture aspects need to be taken into consideration (Feldt et al. 2011). This is challenging as it is not simply the issue of whether there are full (all-to-all) or partial connections between different cell types that can strongly influence the network dynamics. Multiple afferents generally target individual cells (a cell's

convergence), and that cell in turn targets multiple postsynaptic cells (its divergence). This, as well as particular structural motifs (► [“Hippocampus, Model Network Architecture”](#)), can also strongly influence network rhythms.

How Many Cells Are Needed to Represent a Population?

Due to computational constraints, hippocampal network models often incorporate a minimal number of cells for each cell type. However, the “minimal” number of cells needed to represent a population is not clear and will depend on the question being addressed. Thus, many different choices have been made. For example, Gloveli et al. (2005) represent a population of pyramidal cells with a single pyramidal cell model, while Neymotin et al. (2011) represent the pyramidal cell population with 800 cell models. Furthermore, the proportion of the various cell types in the network model could be considered. One may choose the number of each cell population to be proportional to that which is observed experimentally or may make assumptions about the role or influence of a particular cell population during the network rhythm. Regardless, such decisions need to be made.

Overall, important choices must be made about which cell types to include in one's network model, the type of model used to represent them, the connectivity and architecture of the network, and the network size. These choices will ultimately affect the network output and the mechanisms involved in the network model rhythm generation.

Gamma Models

Many models of population gamma have been developed and used (see Buzsáki and Wang 2012 review). Based on both experimental and modeling work, there is a well-developed conceptual understanding of how gamma rhythms are generated in neuronal networks. These mechanisms are described in detail in ► [“Hippocampal Oscillations, Mechanisms \(PING, ING, Sparse\)”](#). Briefly, two distinct gamma-generating mechanisms have been discussed extensively:

interneuron network gamma (ING) and pyramidal-interneuron network gamma (PING). In the ING mechanism, gamma is generated by a network of recurrently connected inhibitory interneurons. This gamma is independent of phasic pyramidal cell firings, although the interneurons do require a depolarizing drive. The frequency and coherence of the gamma generated are dependent on the amount of recurrent connectivity in the network, the excitatory drive to the interneurons, and the decay time constant of the inhibitory postsynaptic potentials (IPSPs). Conversely, the PING mechanism requires the interaction between principal cells and inhibitory interneurons but does not require recurrent connections among the interneurons. PING networks require specific firing ratios between the pyramidal and the interneuron populations, and oscillations only occur when principal cells have high firing rates (i.e., they must fire at or above gamma frequencies). The majority of theta/gamma models created thus far have utilized this PING mechanism. Physiologically, gamma may be generated by a combination of mechanisms, including ING and PING. See the “Further Reading” section for PING/ING model references.

Theta Models

Maccaferri and McBain (1996) showed that a hyperpolarization-activated (h) current in oriens-alveus interneurons is involved in the generation of spontaneous spiking activity at theta frequencies. Since then, these cells have been seen as a potential pacemaker for intrinsic hippocampal theta rhythms. In 2002, Gillies and colleagues produced atropine-resistant theta oscillations in the CA1 region of *in vitro* hippocampal slice preparations by applying a metabotropic glutamate agonist and an α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor blocker. During this pharmacologically induced CA1 theta oscillation, Gillies et al. (2002) implicated oriens-lacunosum-moleculare (O-LM) interneurons, and specifically h-currents in these cells, as a critical component of this theta generation.

Rotstein et al. (2005) constructed an inhibitory interneuron-based hippocampal network model to determine whether h-currents in O-LM interneurons could be responsible for the theta generation described by Gillies et al. (2002). Using single-compartment O-LM cell models (O) with h-channel dynamics, they tested whether a network of two cell models (Fig. 2a) could produce network theta oscillations. They found that although their models individually fired intrinsically at 12 Hz, the two cells could not produce a robust coherent rhythm. When a fast-spiking cell model (I) provided common inhibition to the O cell network (Fig. 2b), it robustly entrained and synchronized the O cells only when I cells were firing at theta frequencies. Furthermore, if feedback was provided from O to I cells (Fig. 2c), the network produced robust and coherent theta oscillations. Their findings did not depend critically on network size, but did on the presence of h-currents in their O cell model and the absence of this current in their I cell model.
